DEDICATED TO THE ADVANCEMENT OF

THE PROFESSION AND ITS ALLIED INDUSTRIES

No part of this publication may be reproduced without permission in writing from ASHRAE, except by a reviewer who may quote brief passages or reproduce illustrations in a review with appropriate credit; nor may any part of this book be reproduced, stored in a retrieval system, or transmitted in any way or by any means—electronic, photocopying, recording, or other—without permission in writing from ASHRAE. Requests for permission should be submitted at www.ashrae.org/permissions.

Volunteer members of ASHRAE Technical Committees and others compiled the information in this handbook, and it is generally reviewed and updated every four years. Comments, criticisms, and suggestions regarding the subject matter are invited. Any errors or omissions in the data should be brought to the attention of the Editor. Additions and corrections to Handbook volumes in print will be published in the Handbook published the year following their verification and, as soon as verified, on the ASHRAE website.

DISCLAIMER

ASHRAE has compiled this publication with care, but ASHRAE has not investigated, and ASHRAE expressly disclaims any duty to investigate, any product, service, process, procedure, design, or the like that may be described herein. The appearance of any technical data or editorial material in this publication does not constitute endorsement, warranty, or guaranty by ASHRAE of any product, service, process, procedure, design, or the like. ASHRAE does not warrant that the information in this publication is free of errors. The entire risk of the use of any information in this publication is assumed by the user.

ISBN 978-1-947192-90-4
ISSN 1523-7230

The paper for this book is both acid- and elemental-chlorine-free and was manufactured with pulp obtained from sources using sustainable forestry practices.

ASHRAE Technical Committees, Task Groups, and Technical Resource Groups

ASHRAE Research: Improving the Quality of Life

Preface

PRINCIPLES

Chapter
1. **Psychrometrics** (TC 1.1, Thermodynamics and Psychrometrics; TC 8.3, Absorption and Heat Operated Machines)
2. **Thermodynamics and Refrigeration Cycles** (TC 1.1)
3. **Fluid Flow** (TC 1.3, Heat Transfer and Fluid Flow)
4. **Heat Transfer** (TC 1.3)
5. **Two-Phase Flow** (TC 1.3)
6. **Mass Transfer** (TC 1.3)
7. **Fundamentals of Control** (TC 1.4, Control Theory and Application)
8. **Sound and Vibration** (TC 2.6, Sound and Vibration)

INDOOR ENVIRONMENTAL QUALITY

Chapter
9. **Thermal Comfort** (TC 2.1, Physiology and Human Environment)
10. **Indoor Environmental Health** (Environmental Health Committee)
11. **Air Contaminants** (TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment)
12. **Odors** (TC 2.3)
13. **Indoor Environmental Modeling** (TC 4.10, Indoor Environmental Modeling)

LOAD AND ENERGY CALCULATIONS

Chapter
14. **Climatic Design Information** (TC 4.2, Climatic Information)
15. **Fenestration** (TC 4.5, Fenestration)
16. **Ventilation and Infiltration** (TC 4.3, Ventilation Requirements and Infiltration)
17. **Residential Cooling and Heating Load Calculations** (TC 4.1, Load Calculation Data and Procedures)
18. **Nonresidential Cooling and Heating Load Calculations** (TC 4.1)
19. **Energy Estimating and Modeling Methods** (TC 4.7, Energy Calculations)

HVAC DESIGN

Chapter
20. **Space Air Diffusion** (TC 5.3, Room Air Distribution)
21. **Duct Design** (TC 5.2, Duct Design)
22. **Pipe Design** (TC 6.1, Hydronic and Steam Equipment and Systems)
23. **Insulation for Mechanical Systems** (TC 1.8, Mechanical Systems Insulation)
24. **Airflow Around Buildings** (TC 4.3)

BUILDING ENVELOPE

Chapter 25. **Heat, Air, and Moisture Control in Building Assemblies—Fundamentals** (TC 4.4, Building Materials and Building Envelope Performance)
26. **Heat, Air, and Moisture Control in Building Assemblies—Material Properties** (TC 4.4)
27. **Heat, Air, and Moisture Control in Building Assemblies—Examples** (TC 4.4)

MATERIALS

Chapter 28. **Combustion and Fuels** (TC 6.10, Fuels and Combustion)
29. **Refrigerants** (TC 3.1, Refrigerants and Secondary Coolants)
30. **Thermophysical Properties of Refrigerants** (TC 3.1)
31. **Physical Properties of Secondary Coolants (Brines)** (TC 3.1)
32. **Sorbents and Desiccants** (TC 8.10, Mechanical and Desiccant Dehumidification Equipment, Heat Pipes and Components)
33. **Physical Properties of Materials** (TC 1.3)

GENERAL

Chapter 34. **Energy Resources** (TC 2.8, Building Environmental Impacts and Sustainability)
35. **Sustainability** (TC 2.8)
36. **Global Climate Change** (TC 2.5, Global Climate Change)
37. **Moisture Management in Buildings** (TC 1.12, Moisture Management in Buildings)
38. **Measurement and Instruments** (TC 1.2, Instruments and Measurements)
39. **Abbreviations and Symbols** (TC 1.6, Terminology)
40. **Units and Conversions** (TC 1.6)
41. **Codes and Standards**

ADDITIONS AND CORRECTIONS

INDEX

Composite index to the 2018 Refrigeration, 2019 HVAC Applications, 2020 HVAC Systems and Equipment, and 2021 Fundamentals volumes

CONTRIBUTORS

In addition to the Technical Committees, the following individuals contributed significantly to this volume. The appropriate chapter numbers follow each contributor's name.

Kashif Nawaz (1, 4, 5)

ASHRAE TECHNICAL COMMITTEES, TASK GROUPS, AND TECHNICAL RESOURCE GROUPS

SECTION 1.0—FUNDAMENTALS AND GENERAL

1.1 Thermodynamics and Psychrometrics
1.2 Instruments and Measurements
1.3 Heat Transfer and Fluid Flow
1.4 Control Theory and Application
1.5 Computer Applications
1.6 Terminology
1.7 Business, Management & General Legal Education
1.8 Mechanical Systems Insulation
1.9 Electrical Systems
1.10 Combined Heat and Power Systems
1.11 Electric Motors and Motor Control
1.12 Moisture Management in Buildings
1.13 Optimization

SECTION 2.0—ENVIRONMENTAL QUALITY

2.1 Physiology and Human Environment
2.2 Plant and Animal Environment
2.3 Gaseous Air Contaminants and Gas Contaminant Removal Equipment
2.4 Particulate Air Contaminants and Particulate Contaminant Removal Equipment
2.5 Global Climate Change
2.6 Sound and Vibration
2.7 Seismic, Wind and Flood Resistant Design
2.8 Building Environmental Impacts and Sustainability
2.9 Ultraviolet Air and Surface Treatment
2.10 Resilience and Security

SECTION 3.0—MATERIALS AND PROCESSES

3.1 Refrigerants and Secondary Coolants
3.2 Refrigerant System Chemistry and Contaminant Control
3.4 Lubrication
3.6 Water Treatment
3.8 Refrigerant Containment

SECTION 4.0—LOAD CALCULATIONS AND ENERGY REQUIREMENTS

4.1 Load Calculation Data and Procedures
4.2 Climatic Information
4.3 Ventilation Requirements and Infiltration
4.4 Building Materials and Building Envelope Performance
4.5 Fenestration
4.7 Energy Calculations
4.10 Indoor Environmental Modeling
TRG4 Indoor Air Quality Procedure Development

SECTION 5.0—VENTILATION AND AIR DISTRIBUTION

5.1 Fans
5.2 Duct Design
5.3 Room Air Distribution
5.4 Industrial Process Air Cleaning (Air Pollution Control)
5.5 Air-to-Air Energy Recovery
5.6 Control of Fire and Smoke
5.7 Evaporative Cooling
5.9 Enclosed Vehicular Facilities
5.10 Kitchen Ventilation
5.11 Humidifying Equipment

SECTION 6.0—HEATING EQUIPMENT, HEATING AND COOLING SYSTEMS AND APPLICATIONS

6.1 Hydronic and Steam Equipment and Systems
6.2 District Energy
6.3 Central Forced Air Heating and Cooling Systems
6.5 Radiant Heating and Cooling
6.6 Service Water Heating Systems
6.7 Solar and Other Renewable Energies
6.8 Geothermal Heat Pump and Energy Recovery Applications
6.9 Thermal Storage
6.10 Fuels and Combustion

SECTION 7.0—BUILDING PERFORMANCE

7.1 Integrated Building Design
7.2 HVAC&R Construction & Design Build Technologies
7.3 Operation, Maintenance and Cost Management
7.4 Exergy Analysis for Sustainable Buildings (EXER)
7.5 Smart Building Systems
7.6 Building Energy Performance
7.7 Testing and Balancing
7.8 Building Commissioning

SECTION 8.0—AIR-CONDITIONING AND REFRIGERATION SYSTEM COMPONENTS

8.1 Positive Displacement Compressors
8.2 Centrifugal Machines
8.3 Absorption and Heat Operated Machines
8.4 Air-to-Refrigerant Heat Transfer Equipment
8.5 Liquid-to-Refrigerant Heat Exchangers
8.6 Cooling Towers and Evaporative Condensers
8.7 Variable Refrigerant Flow (VRF)
8.8 Refrigerant System Controls and Accessories
8.9 Residential Refrigerators and Food Freezers
8.10 Mechanical and Desiccant Dehumidification Equipment, Heat Pipes and Components
8.11 Unitary and Room Air Conditioners and Heat Pumps

SECTION 9.0—BUILDING APPLICATIONS

9.1 Large Building Air-Conditioning Systems
9.2 Industrial Air Conditioning and Ventilation
9.3 Transportation Air Conditioning
9.6 Healthcare Facilities
9.7 Educational Facilities
9.8 Large Building Air-Conditioning Applications
9.9 Mission Critical Facilities, Data Centers, Technology Spaces and Electronic Equipment
9.10 Laboratory Systems
9.11 Clean Spaces
9.12 Tall Buildings
TRG9 Cold Climate Design

SECTION 10.0—REFRIGERATION SYSTEMS

10.1 Custom Engineered Refrigeration Systems
10.2 Refrigeration Applications
10.3 Refrigerant Piping, Controls, and Accessories
10.6 Transport Refrigeration
10.7 Commercial Food and Beverage Refrigeration Equipment

SECTION MTG—MULTIDISCIPLINARY TASK GROUPS

ASHRAE Research: Improving the Quality of Life

ASHRAE is the world's foremost technical society in the fields of heating, ventilation, air conditioning, and refrigeration. Its members worldwide are individuals who share ideas, identify needs, support research, and write the industry's standards for testing and practice. The result is that engineers are better able to keep indoor environments safe and productive while protecting and preserving the outdoors for generations to come.

One of the ways that ASHRAE supports its members' and industry's need for information is through ASHRAE Research. Thousands of individuals and companies support ASHRAE Research annually, enabling ASHRAE to report new data about material properties and building physics and to promote the application of innovative technologies.

Chapters in the ASHRAE Handbook are updated through the experience of members of ASHRAE Technical Committees and through results of ASHRAE Research reported at ASHRAE conferences and published in ASHRAE special publications, *ASHRAE Transactions*, and ASHRAE's journal of archival research, *Science and Technology for the Built Environment*.

For information about ASHRAE Research or to become a member, contact ASHRAE, 180 Technology Parkway, Peachtree Corners, GA 30092; telephone: 404-636-8400; www.ashrae.org.

Preface

The 2021 *ASHRAE Handbook—Fundamentals* covers basic principles and data used in the HVAC&R industry. The ASHRAE Technical Committees that prepare these chapters provide new information, clarify existing content, delete obsolete materials, and reorganize chapters to make the Handbook more understandable and easier to use.

Eligible ASHRAE members can download PDFs of this volume, in either I-P or SI units and either as a complete volume or by individual chapter, by logging into technologyportal.ashrae.org.

This edition includes a new chapter on global climate change. Individual Handbook chapters have long addressed sustainability, global warming potential, greenhouse gases, recycling, and reclamation as they apply to those chapters' specific topics, but ASHRAE is pleased to present an entirely new chapter dedicated entirely to designing and operating in a changing world environment.

In addition to the new chapter, this volume's content has been extensively updated since the 2017 edition. **Chapter 14, Climatic Design Information,** for instance, has expanded its coverage and added data from 1119 new weather stations around the world, for a total of 9237 stations.

This volume is published, as a bound print volume and in electronic format as PDF and online, in two editions: one using inch-pound (I-P) units of measurement, the other using the International System of Units (SI).

Corrections to the 2018, 2019, and 2020 Handbook volumes can be found on the ASHRAE website at www.ashrae.org and in the Additions and Corrections section of this volume. Corrections for this volume will be listed in subsequent volumes and on the ASHRAE website.

Reader comments are enthusiastically invited. To suggest improvements for a chapter, **please comment using the form on the ASHRAE website** or write to Handbook Editor, ASHRAE, 180 Technology Parkway, Peachtree Corners, GA 30092, fax 678-539-2168, or e-mail hkennedy@ashrae.org.

CHAPTER 1

PSYCHROMETRICS

Composition of Dry and Moist Air 1.1
U.S. Standard Atmosphere 1.1
Thermodynamic Properties of Moist Air 1.2
Thermodynamic Properties of Water at Saturation 1.4
Humidity Parameters 1.8
Perfect Gas Relationships for Dry and Moist Air 1.8
Thermodynamic Wet-Bulb and Dew-Point Temperature 1.9
Numerical Calculation of Moist Air Properties 1.10
Psychrometric Charts 1.10
Typical Air-Conditioning Processes 1.12
Transport Properties of Moist Air 1.15
Symbols 1.15

PSYCHROMETRICS uses thermodynamic properties to analyze conditions and processes involving moist air. This chapter discusses perfect gas relations and their use in common heating, cooling, and humidity control problems. Formulas developed by Herrmann et al. (2009) may be used where greater precision is required.

Herrmann et al. (2009), Hyland and Wexler (1983a, 1983b), and Nelson and Sauer (2002) developed formulas for thermodynamic properties of moist air and water modeled as real gases. However, perfect gas relations can be substituted in most air-conditioning problems. Kuehn et al. (1998) showed that errors are less than 0.7% in calculating humidity ratio, enthalpy, and specific volume of saturated air at standard atmospheric pressure for a temperature range of –50 to 50°C. Furthermore, these errors decrease with decreasing pressure.

Hermann et al. (2020) prepared formulas for transport properties of moist air.

1. COMPOSITION OF DRY AND MOIST AIR

Atmospheric air contains many gaseous components as well as water vapor and miscellaneous contaminants (e.g., smoke, pollen, and gaseous pollutants not normally present in free air far from pollution sources).

Dry air is atmospheric air with all water vapor and contaminants removed. Its composition is relatively constant, but small variations in the amounts of individual components occur with time, geographic location, and altitude. Harrison (1965) lists the approximate percentage composition of dry air by volume as: nitrogen, 78.084; oxygen, 20.9476; argon, 0.934; neon, 0.001818; helium, 0.000524; methane, 0.00015; sulfur dioxide, 0 to 0.0001; hydrogen, 0.00005; and minor components such as krypton, xenon, and ozone, 0.0002. Harrison (1965) and Hyland and Wexler (1983a) used a value 0.0314 (circa 1955) for carbon dioxide. Carbon dioxide reached 0.0379 in 2005, is currently increasing by 0.00019 percent per year and is projected to reach 0.0438 in 2036 (Gatley et al. 2008; Keeling and Whorf 2005a, 2005b). Increases in carbon dioxide are offset by decreases in oxygen; consequently, the oxygen percentage in 2036 is projected to be 20.9352. Using the projected changes, the relative molecular mass for dry air for at least the first half of the 21st century is 28.966, based on the carbon-12 scale. The gas constant for dry air using the Mohr and Taylor (2005) value for the universal gas constant is

$$R_{da} = 8314.472/28.966 = 287.042 \text{ J/(kg}_{da}\cdot\text{K)} \quad (1)$$

Moist air is a binary (two-component) mixture of dry air and water vapor. The amount of water vapor varies from zero (dry air) to a maximum that depends on temperature and pressure. **Saturation** is a state of neutral equilibrium between moist air and the condensed water phase (liquid or solid); unless otherwise stated, it assumes a flat interface surface between moist air and the condensed phase. Saturation conditions change when the interface radius is very small (e.g., with ultrafine water droplets). According to the Industrial Formulation IAPWS-IF97 (R7-97 2012), the relative molecular mass of water is 18.015 257. The gas constant for water vapor is

$$R_w = 8314.472/18.015\,257 = 461.524 \text{ J/(kg}_w\cdot\text{K)} \quad (2)$$

2. U.S. STANDARD ATMOSPHERE

The temperature and barometric pressure of atmospheric air vary considerably with altitude as well as with local geographic and weather conditions. The standard atmosphere gives a standard of reference for estimating properties at various altitudes. At sea level, standard temperature is 15°C; standard barometric pressure is 101.325 kPa. Temperature is assumed to decrease linearly with increasing altitude throughout the troposphere (lower atmosphere), and to be constant in the lower reaches of the stratosphere. The lower atmosphere is assumed to consist of dry air that behaves as a perfect gas. Gravity is also assumed constant at the standard value, 9.806 65 m/s^2. Table 1 summarizes property data for altitudes to 10 000 m.

Pressure values in Table 1 may be calculated from

$$p = 101.325(1 - 2.25577 \times 10^{-5}Z)^{5.2559} \quad (3)$$

The equation for temperature as a function of altitude is

$$t = 15 - 0.0065Z \quad (4)$$

where

Z = altitude, m
p = barometric pressure, kPa
t = temperature, °C

Equations (3) and (4) are accurate from –5000 m to 11 000 m. For higher altitudes, comprehensive tables of barometric pressure and other physical properties of the standard atmosphere, in both SI and I-P units, can be found in NASA (1976).

3. THERMODYNAMIC PROPERTIES OF MOIST AIR

Table 2, calculated using ASHRAE's (2021) LibHuAirProp software (based on ASHRAE RP-1485; Hermann et al. 2009, 2020), shows values of thermodynamic properties of saturated moist air and dry air at 101.325 kPa and temperatures from –60 to 90°C.

The following properties are shown in Table 2:

t = Celsius temperature, based on the ITS-90 and expressed relative to absolute temperature T in kelvins (K) by the following relation:

$$T = t + 273.15$$

The preparation of this chapter is assigned to TC 1.1, Thermodynamics and Psychrometrics.

9000	–43.5	30.742
10 000	–50	26.436

Source: Adapted from NASA (1976).

W_s = humidity ratio at saturation; gaseous phase (moist air) exists in equilibrium with condensed phase (liquid or solid) at given temperature and pressure (standard atmospheric pressure). At given values of temperature and pressure, humidity ratio W can have any value from zero to W_s.

v_{da} = specific volume of dry air, m^3/kg_{da}.

$v_{as} = v_s - v_{da}$, difference between specific volume of moist air at saturation and that of dry air, m^3/kg_{da}, at same pressure and temperature.

v_s = specific volume of moist air at saturation, m^3/kg_{da}.

h_{da} = specific enthalpy of dry air, kJ/kg_{da}. In Table 2, h_{da} is assigned a value of 0 at 0°C and standard atmospheric pressure.

$h_{as} = h_s - h_{da}$, difference between specific enthalpy of moist air at saturation and that of dry air, kJ/kg_{da}, at same pressure and temperature.

h_s = specific enthalpy of moist air at saturation, kJ/kg_{da}.

s_{da} = specific entropy of dry air, $kJ/(kg_{da}\cdot K)$. In Table 2, s_{da} is assigned a value of 0 at 0°C and standard atmospheric pressure.

s_s = specific entropy of moist air at saturation $kJ/(kg_{da}\cdot K)$.

4. THERMODYNAMIC PROPERTIES OF WATER AT SATURATION

Table 3 shows thermodynamic properties of water at saturation for temperatures from –60 to 160°C, calculated using ASHRAE (2021) LibHuAirProp software, based on IAPWS formulations described in IAPWS R7-97 (2012), R10-06 (2009), and R14-08 (2011). The internal energy and entropy of saturated liquid water are both assigned the value zero at the triple point, 0.01°C. Between the triple-point and critical-point temperatures of water, both **saturated liquid** and **saturated vapor** may coexist in equilibrium; below the triple-point temperature, both **saturated ice** and **saturated vapor** may coexist in equilibrium.

Table 2 Thermodynamic Properties of Saturated Moist and Dry Air at Standard Atmospheric Pressure, 101.325 kPa

		Specific Volume, m^3/kg_{da}		Specific Enthalpy, kJ/kg_{da}		Specific Heat Capacity, $kJ/(kg\cdot K)$		Specific Entropy, $kJ/(kg_{da}\cdot K)$

The following properties are shown in Table 3:

t = temperature in degrees Celsius based on ITS-90 and expressed relative to absolute temperature T in degrees Kelvin by the following relation:

$$T = (°C + 273.15)$$

p_{ws} = absolute pressure of water (solid, liquid, or vapor) at saturation or sublimation temperature t, kPa
v_i = specific volume of saturated solid (ice), m^3/kg
v_f = specific volume of saturated liquid (water), m^3/kg
v_g = specific volume of saturated vapor (steam), m^3/kg
h_i = specific enthalpy of saturated solid (ice), kJ/kg
h_f = specific enthalpy of saturated liquid (water),
h_g = specific enthalpy of saturated vapor (steam), kJ/kg
$c_{p,i}$ = specific isobaric heat capacity of saturated solid (ice), kJ/(kg·K)
$c_{p,f}$ = specific isobaric heat capacity of saturated liquid (water), kJ/(kg·K)
$c_{p,g}$ = specific isobaric heat capacity of saturated vapor (steam), kJ/(kg·K)
s_i = specific entropy of saturated solid (ice), kJ/(kg·K)
s_f = specific entropy of saturated liquid (water),
s_g = specific entropy of saturated vapor (steam), kJ/(kg·K)

The **water vapor saturation pressure** is required to determine a number of moist air properties, principally the saturation humidity ratio. Values may be obtained from Table 3 or calculated from formulas given by IPAWS R7-97(2012) and R14-08 (2011).

The saturation (sublimation) pressure over **ice** for the temperature range of –100 to 0°C is given by

$$\ln p_{ws} = C_1/T + C_2 + C_3T + C_4T^2 + C_5T^3 + C_6T^4 + C_7 \ln T \quad (5)$$

where

C_1 = –5.674 535 9 E+03
C_2 = 6.392 524 7 E+00
C_3 = –9.677 843 0 E–03
C_4 = 6.221 570 1 E–07
C_5 = 2.074 782 5 E–09
C_6 = –9.484 024 0 E–13
C_7 = 4.163 501 9 E+00

The saturation pressure over **liquid water** for the temperature range of 0 to 200°C is given by

$$\ln p_{ws} = C_8/T + C_9 + C_{10}T + C_{11}T^2 + C_{12}T^3 + C_{13} \ln T \quad (6)$$

where

C_8 = –5.800 220 6 E+03
C_9 = 1.391 499 3 E+00
C_{10} = –4.864 023 9 E–02
C_{11} = 4.176 476 8 E–05
C_{12} = –1.445 209 3 E–08
C_{13} = 6.545 967 3 E+00

In both Equations (5) and (6),

p_{ws} = saturation pressure, Pa
T = absolute temperature, K = °C + 273.15

The coefficients of Equations (5) and (6) were derived from the Hyland-Wexler equations. Because of rounding errors in the derivations and in some computers' calculating precision, results from Equations (5) and (6) may not agree precisely with Table 3 values.

The vapor pressure p_s of water in saturated moist air differs negligibly from the saturation vapor pressure p_{ws} of pure water at the same temperature. Consequently, p_s can be used in equations in place of p_{ws} with very little error:

$$p_s = x_{ws}\, p$$

where x_{ws} is the mole fraction of water vapor in saturated moist air at temperature t and pressure p, and p is the total barometric pressure of moist air.

5. HUMIDITY PARAMETERS

Basic Parameters

Humidity ratio W (or **mixing ratio**) of a given moist air sample is defined as the ratio of the mass of water vapor to the mass of dry air in the sample:

$$W = M_w/M_{da} \tag{7}$$

W equals the mole fraction ratio x_w/x_{da} multiplied by the ratio of molecular masses (18.015 268/28.966 = 0.621 945):

$$W = 0.621\ 945 x_w/x_{da} \tag{8}$$

Specific humidity γ is the ratio of the mass of water vapor to total mass of the moist air sample:

$$\gamma = M_w/(M_w + M_{da}) \tag{9a}$$

In terms of the humidity ratio,

$$\gamma = W/(1 + W) \tag{9b}$$

Absolute humidity (alternatively, water vapor density) d_v is the ratio of the mass of water vapor to total volume of the sample:

$$d_v = M_w/V \tag{10}$$

Density ρ of a moist air mixture is the ratio of total mass to total volume:

$$\rho = (M_{da} + M_w)/V = (1/v)(1 + W) \tag{11}$$

where v is the moist air specific volume, m^3/kg_{da}, as defined by Equation (24).

Humidity Parameters Involving Saturation

The following definitions of humidity parameters involve the concept of moist air saturation:

Saturation humidity ratio $W_s(t, p)$ is the humidity ratio of moist air saturated with respect to water (or ice) at the same temperature t and pressure p.

Relative humidity ϕ is the ratio of the actual water vapor partial pressure in moist air at the dew-point pressure and temperature to the reference saturation water vapor partial pressure at the dry-bulb pressure and temperature:

$$\phi = (p_{wv-enh}/p_{wvs-ref}|_{p,t}) = [f(p, t_{dp})e(t_{dp})]/[f(p, t_{db})e(t_{db})] \tag{12}$$

Note that Equations (12) and (22) have been revised so that they cover both the normal range of relative humidity where $e(t_{db}) < p$ and the extended range (e.g., atmospheric pressure drying kilns) where $e(t_{db}) \geq p$. The definitions in earlier editions applied only to the normal range.

Dew-point temperature t_d is the temperature of moist air saturated at pressure p, with the same humidity ratio W as that of the given sample of moist air. It is defined as the solution $t_d(p, W)$ of the following equation:

$$W_s(p, t_d) = W \tag{13}$$

Thermodynamic wet-bulb temperature t^* is the temperature at which water (liquid or solid), by evaporating into moist air at dry-bulb temperature t and humidity ratio W, can bring air to saturation adiabatically at the same temperature t^* while total pressure p is constant. This parameter is considered separately in the section on Thermodynamic Wet-Bulb and Dew-Point Temperature.

6. PERFECT GAS RELATIONSHIPS FOR DRY AND MOIST AIR

When moist air is considered a mixture of independent perfect gases (i.e., dry air and water vapor), each is assumed to obey the perfect gas equation of state as follows:

$$\text{Dry air:} \qquad p_{da}V = n_{da}RT \tag{14}$$

$$\text{Water vapor:} \qquad p_wV = n_wRT \tag{15}$$

where

p_{da} = partial pressure of dry air
p_w = partial pressure of water vapor
V = total mixture volume
n_{da} = number of moles of dry air
n_w = number of moles of water vapor
R = universal gas constant, 8314.472 J/(kmol·K)
T = absolute temperature, K

The mixture also obeys the perfect gas equation:

$$pV = nRT \tag{16}$$

or

$$(p_{da} + p_w)V = (n_{da} + n_w)RT \tag{17}$$

where $p = p_{da} + p_w$ is the total mixture pressure and $n = n_{da} + n_w$ is the total number of moles in the mixture. From Equations (14) to (17), the mole fractions of dry air and water vapor are, respectively,

$$x_{da} = p_{da}/(p_{da} + p_w) = p_{da}/p \tag{18}$$

and

$$x_w = p_w/(p_{da} + p_w) = p_w/p \tag{19}$$

From Equations (8), (18), and (19), the **humidity ratio** W is

$$W = 0.621\ 945\frac{p_w}{p - p_w} \tag{20}$$

The **saturation humidity ratio** W_s is

$$W_s = 0.621\ 945\frac{p_{ws}}{p - p_{ws}} \tag{21}$$

The term p_{ws} represents the saturation pressure of water vapor in the absence of air at the given temperature t. This pressure p_{ws} is a function only of temperature and differs slightly from the vapor pressure of water in saturated moist air.

The **relative humidity** ϕ is defined in Equation (12). Using the second equality and eliminating the enhancement factors, which are not applicable using the perfect gas assumption, gives

$$\phi = e(t_{dp})/e(t_{db}) \tag{22}$$

Substituting Equation (21) for W_s into Equation (13),

Licensed for single user. © 2021 ASHRAE, Inc.

$$\phi = \frac{\mu}{1-(1-\mu)(p_{ws}/p)} \tag{23}$$

where μ is degree of saturation W/W_s, dimensionless.

Both ϕ and μ are zero for dry air and unity for saturated moist air. At intermediate states, their values differ, substantially at higher temperatures.

The **specific volume** v of a moist air mixture is expressed in terms of a unit mass of dry air:

$$v = V/M_{da} = V/(28.966 n_{da}) \tag{24}$$

where V is the total volume of the mixture, M_{da} is the total mass of dry air, and n_{da} is the number of moles of dry air. By Equations (14) and (24), with the relation $p = p_{da} + p_w$,

$$v = \frac{RT}{28.966(p-p_w)} = \frac{R_{da}T}{p-p_w} \tag{25}$$

Using Equation (18),

$$v = \frac{RT(1+(1.607\ 858)W)}{28.966p} = \frac{R_{da}T(1+(1.607\ 858)W)}{p} \tag{26}$$

In Equations (25) and (26), v is specific volume, T is absolute temperature, p is total pressure, p_w is partial pressure of water vapor, and W is humidity ratio.

In specific units, Equation (26) may be expressed as

$$v = 0.287\ 042(t+273.15)(1+1.607\ 858W)/p$$

where

v = specific volume, m^3/kg_{da}
t = dry-bulb temperature, °C
W = humidity ratio, kg_w/kg_{da}
p = total pressure, kPa

The **enthalpy** of a mixture of perfect gases equals the sum of the individual partial enthalpies of the components. Therefore, the specific enthalpy of moist air can be written as follows:

$$h = h_{da} + Wh_g \tag{27}$$

where h_{da} is the specific enthalpy for dry air in kJ/kg_{da} and h_g is the specific enthalpy for saturated water vapor in kJ/kg_w at the mixture's temperature. As an approximation,

$$h_{da} \approx 1.006t \tag{28}$$

$$h_g \approx 2501 + 1.86t \tag{29}$$

where t is the dry-bulb temperature in °C. The moist air specific enthalpy in kJ/kg_{da} then becomes

$$h = 1.006t + W(2501 + 1.86t) \tag{30}$$

7. THERMODYNAMIC WET-BULB AND DEW-POINT TEMPERATURE

For any state of moist air, a temperature t^* exists at which liquid (or solid) water evaporates into the air to bring it to saturation at exactly this same temperature and total pressure (Harrison 1965). During adiabatic saturation, saturated air is expelled at a temperature equal to that of the injected water. In this constant-pressure process,

- Humidity ratio increases from initial value W to W_s^*, corresponding to saturation at temperature t^*
- Enthalpy increases from initial value h to h_s^*, corresponding to saturation at temperature t^*
- Mass of water added per unit mass of dry air is $(W_s^* - W)$, which adds energy to the moist air of amount $(W_s^* - W)h_w^*$, where h_w^* denotes specific enthalpy in kJ/kg_w of water added at temperature t^*

Therefore, if the process is strictly adiabatic, conservation of enthalpy at constant total pressure requires that

$$h + (W_s^* - W)h_w^* = h_s^* \tag{31}$$

W_s^*, h_w^*, and h_s^* are functions only of temperature t^* for a fixed value of pressure. The value of t^* that satisfies Equation (31) for given values of h, W, and p is the **thermodynamic wet-bulb temperature**.

A **psychrometer** consists of two thermometers; one thermometer's bulb is covered by a wick that has been thoroughly wetted with water. When the wet bulb is placed in an airstream, water evaporates from the wick, eventually reaching an equilibrium temperature called the **wet-bulb temperature**. This process is not one of adiabatic saturation, which defines the thermodynamic wet-bulb temperature, but one of simultaneous heat and mass transfer from the wet bulb. The fundamental mechanism of this process is described by the Lewis relation [Equation (40) in Chapter 6]. Fortunately, only small corrections must be applied to wet-bulb thermometer readings to obtain the thermodynamic wet-bulb temperature.

As defined, thermodynamic wet-bulb temperature is a unique property of a given moist air sample independent of measurement techniques.

Equation (31) is exact because it defines the thermodynamic wet-bulb temperature t^*. Substituting the approximate perfect gas relation [Equation (30)] for h, the corresponding expression for h_s^*, and the approximate relation for saturated liquid water

$$h_w^* \approx 4.186t^* \tag{32}$$

into Equation (31), and solving for the humidity ratio,

$$W = \frac{(2501 - 2.326t^*)W_s^* - 1.006(t-t^*)}{2501 + 1.86t - 4.186t^*} \tag{33}$$

where t and t^* are in °C. Below freezing, the corresponding equations are

$$h_w^* \approx -333.4 + 2.1t^* \tag{34}$$

$$W = \frac{(2830 - 0.24t^*)W_s^* - 1.006(t-t^*)}{2830 + 1.86t - 2.1t^*} \tag{35}$$

A wet/ice-bulb thermometer is imprecise when determining moisture content at 0°C.

The **dew-point temperature** t_d of moist air with humidity ratio W and pressure p was defined as the solution $t_d(p, W)$ of $W_s(p, t_d)$. For perfect gases, this reduces to

$$p_{ws}(t_d) = p_w = (pW)/(0.621\ 945 + W) \tag{36}$$

where p_w is the water vapor partial pressure for the moist air sample and $p_{ws}(t_d)$ is the saturation vapor pressure at temperature t_d. The saturation vapor pressure is obtained from Table 3 or by using Equation (5) or (6). Alternatively, the dew-point temperature can be calculated directly by one of the following equations (Peppers 1988):

Between dew points of 0 and 93°C,

$$t_d = C_{14} + C_{15}\alpha + C_{16}\alpha^2 + C_{17}\alpha^3 + C_{18}(p_w)^{0.1984} \tag{37}$$

Below 0°C,

$$t_d = 6.09 + 12.608\alpha + 0.4959\alpha^2 \tag{38}$$

where

t_d = dew-point temperature, °C
$\alpha = \ln p_w$

Licensed for single user. © 2021 ASHRAE, Inc.

p_w = water vapor partial pressure, kPa
C_{14} = 6.54
C_{15} = 14.526
C_{16} = 0.7389
C_{17} = 0.09486
C_{18} = 0.4569

8. NUMERICAL CALCULATION OF MOIST AIR PROPERTIES

The following are outlines, citing equations and tables already presented, for calculating moist air properties using perfect gas relations. These relations are accurate enough for most engineering calculations in air-conditioning practice, and are readily adapted to either hand or computer calculating methods. For more details, refer to Tables 15 through 18 in Chapter 1 of Olivieri (1996). Graphical procedures are discussed in the section on Psychrometric Charts.

SITUATION 1.

Given: Dry-bulb temperature t, Wet-bulb temperature t^*, Pressure p

To Obtain	Use	Comments
$p_{ws}(t^*)$	Table 3 or Equation (5) or (6)	Sat. press. for temp. t^*
W_s^*	Equation (21)	Using $p_{ws}(t^*)$

Moist Air Property Tables for Standard Pressure

Table 2 shows thermodynamic properties for standard atmospheric pressure at temperatures from –60 to 90°C calculated using the ASHRAE RP-1485 (Herrmann et al. 2009) research project numerical model. Properties of intermediate moist air states can be calculated using the degree of saturation μ:

$$\text{Volume} \quad v = v_{da} + \mu v_{as} \tag{39}$$

$$\text{Enthalpy} \quad h = h_{da} + \mu h_{as} \tag{40}$$

These equations are accurate to about 350°C. At higher temperatures, errors can be significant.

9. PSYCHROMETRIC CHARTS

A psychrometric chart graphically represents the thermodynamic properties of moist air.

The choice of coordinates for a psychrometric chart is arbitrary. A chart with coordinates of enthalpy and humidity ratio provides convenient graphical solutions of many moist air problems with a minimum of thermodynamic approximations. ASHRAE developed five such psychrometric charts. Chart 1 is shown as Figure 1; the others may be obtained through ASHRAE.

Charts 1, 2, 3 and 4 are for sea-level pressure (101.325 kPa). Chart 5 is for 750 m altitude (92.634 kPa), Chart 6 is for 1500 m altitude (84.54 kPa), and Chart 7 is for 2250 m altitude (77.058 kPa). All charts use oblique-angle coordinates of enthalpy and humidity ratio, and are consistent with the data of Table 2 and the properties computation methods of Hyland and Wexler (1983a) and ASHRAE research project RP-1485. Palmatier (1963) describes the geometry of chart construction applying specifically to Charts 1 and 4.

The dry-bulb temperature ranges covered by the charts are

Charts 1, 5, 6, 7	Normal temperature	0 to 50°C
Chart 2	Low temperature	–40 to 10°C
Chart 3	High temperature	10 to 120°C
Chart 4	Very high temperature	100 to 200°C

Charts 8 to 16 are for 200 to 320°C and cover the same pressures as 1, 5, 6, and 7 plus the additional pressures of 0.2, 0.5,1.0, 2.0, and 5.0 MPa. They were produced by Nelson and Sauer (2002) and are available as a download with Gatley (2013).

Psychrometric properties or charts for other barometric pressures can be derived by interpolation. Sufficiently exact values for most purposes can be derived by methods described in the section on Perfect Gas Relationships for Dry and Moist Air. Constructing charts for altitude conditions has been discussed by Haines (1961), Karig (1946), and Rohsenow (1946).

Comparison of charts 1 and 6 by overlay reveals the following:

- The dry-bulb lines coincide.
- Wet-bulb lines for a given temperature originate at the intersections of the corresponding dry-bulb line and the two saturation curves, and they have the same slope.
- Humidity ratio and enthalpy for a given dry- and wet-bulb temperature increase with altitude, but there is little change in relative humidity.
- Volume changes rapidly; for a given dry-bulb and humidity ratio, it is practically inversely proportional to barometric pressure.

The following table compares properties at sea level (chart 1) and 1500 m (chart 6):

Chart No.	db	wb	*h*	*W*	rh	*v*
1	40	30	99.5	23.0	49	0.920
6	40	30	114.1	28.6	50	1.111

Figure 1 shows humidity ratio lines (horizontal) for the range from 0 (dry air) to 30 grams moisture per kilogram dry air. Enthalpy

Licensed for single user. © 2021 ASHRAE, Inc.

lines are oblique lines across the chart precisely parallel to each other.

Dry-bulb temperature lines are straight, not precisely parallel to each other, and inclined slightly from the vertical position. Thermodynamic wet-bulb temperature lines are oblique and in a slightly different direction from enthalpy lines. They are straight but are not precisely parallel to each other.

Relative humidity lines are shown in intervals of 10%. The saturation curve is the line of 100% rh, whereas the horizontal line for $W = 0$ (dry air) is the line for 0% rh.

Specific volume lines are straight but are not precisely parallel to each other.

A narrow region above the saturation curve has been developed for fog conditions of moist air. This two-phase region represents a mechanical mixture of saturated moist air and liquid water, with the two components in thermal equilibrium. Isothermal lines in the fog region coincide with extensions of thermodynamic wet-bulb temperature lines. If required, the fog region can be further expanded by extending humidity ratio, enthalpy, and thermodynamic wet-bulb temperature lines.

The protractor to the left of the chart shows two scales: one for sensible/total heat ratio, and one for the ratio of enthalpy difference to humidity ratio difference. The protractor is used to establish the direction of a condition line on the psychrometric chart.

Example 1 shows use of the ASHRAE psychrometric chart to determine moist air properties.

Example 1. Moist air exists at 40°C dry-bulb temperature, 20°C thermodynamic wet-bulb temperature, and 101.325 kPa pressure. Determine the humidity ratio, enthalpy, dew-point temperature, relative humidity, and specific volume.

Solution: Locate state point on chart 1 (Figure 1) at the intersection of 40°C dry-bulb temperature and 20°C thermodynamic wet-bulb temperature lines. Read **humidity ratio** $W = 6.5$ g_w/kg_{da}.

The **enthalpy** can be found by using two triangles to draw a line parallel to the nearest enthalpy line (60 kJ/kg_{da}) through the state point to the nearest edge scale. Read $h = 56.7$ kJ/kg_{da}.

Dew-point temperature can be read at the intersection of $W = 6.5$ g_w/kg_{da} with the saturation curve. Thus, $t_d = 7$°C.

Relative humidity ϕ can be estimated directly. Thus, $\phi = 14\%$.

Specific volume can be found by linear interpolation between the volume lines for 0.88 and 0.90 m^3/kg_{da}. Thus, $v = 0.896$ m^3/kg_{da}.

10. TYPICAL AIR-CONDITIONING PROCESSES

The ASHRAE psychrometric chart can be used to solve numerous process problems with moist air. Its use is best explained through illustrative examples. In each of the following examples, the process takes place at a constant total pressure of 101.325 kPa.

Moist Air Sensible Heating or Cooling

Adding heat alone to or removing heat alone from moist air is represented by a horizontal line on the ASHRAE chart, because the humidity ratio remains unchanged.

Figure 2 shows a device that adds heat to a stream of moist air. For steady-flow conditions, the required rate of heat addition is

$$ {}_1q_2 = \dot{m}_{da}(h_2 - h_1) \tag{41}$$

Example 2. Moist air, saturated at 2°C, enters a heating coil at a rate of 10 m^3/s. Air leaves the coil at 40°C. Find the required rate of heat addition.

Solution: Figure 3 schematically shows the solution. State 1 is located on the saturation curve at 2°C. Thus, $h_1 = 13.0$ kJ/kg_{da}, $W_1 = 4.38$ g_w/kg_{da}, and $v_1 = 0.785$ m^3/kg_{da}. State 2 is located at the intersection of $t = 40$°C and $W_2 = W_1 = 4.38$ g_{wT}/kg_{da}. Thus, $h_2 = 51.5$ kJ/kg_{da}. The mass flow of dry air is

$$\dot{m}_{da} = 10/0.785 = 12.74 \text{ kg}_{da}/\text{s}$$

From Equation (41),

$${}_1q_2 = 12.74(51.5 - 13.0) = 490 \text{ kW}$$

Moist Air Cooling and Dehumidification

Moisture condensation occurs when moist air is cooled to a temperature below its initial dew point. Figure 4 shows a schematic cooling coil where moist air is assumed to be uniformly processed. Although water can be removed at various temperatures ranging from the initial dew point to the final saturation temperature, it is assumed that condensed water is cooled to the final air temperature t_2 before it drains from the system.

For the system in Figure 4, the steady-flow energy and material balance equations are

$$\dot{m}_{da}h_1 = \dot{m}_{da}h_2 + {}_1q_2 + \dot{m}_w h_{w2}$$
$$\dot{m}_{da}W_1 = \dot{m}_{da}W_2 + \dot{m}_w$$

Thus,

$$\dot{m}_w = \dot{m}_{da}(W_1 - W_2) \tag{42}$$

$${}_1q_2 = \dot{m}_{da}[(h_1 - h_2) - (W_1 - W_2)h_{w2}] \tag{43}$$

Example 3. Moist air at 30°C dry-bulb temperature and 50% rh enters a cooling coil at 5 m^3/s and is processed to a final saturation condition at 10°C. Find the kW of refrigeration required.

Solution: Figure 5 shows the schematic solution. State 1 is located at the intersection of $t = 30$°C and $\phi = 50\%$. Thus, $h_1 = 64.3$ kJ/kg_{da}, $W_1 = 13.3$ g_w/kg_{da}, and $v_1 = 0.877$ m^3/kg_{da}. State 2 is located on the sat-

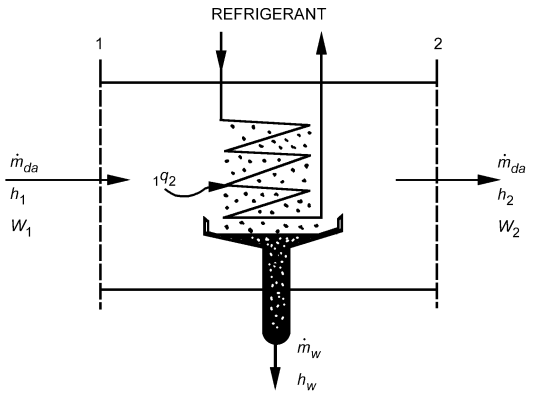

Fig. 4 Schematic of Device for Cooling Moist Air

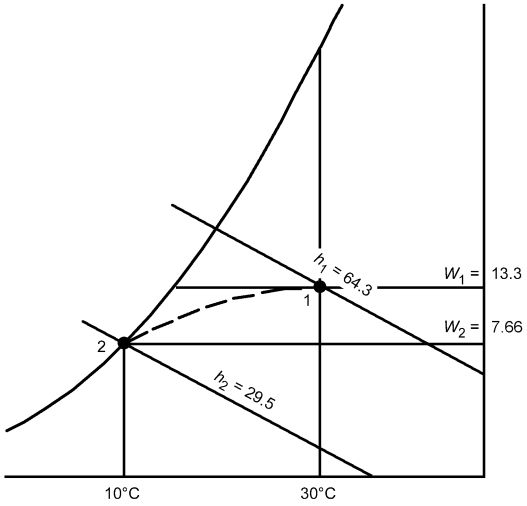

Fig. 5 Schematic Solution for Example 3

uration curve at 10°C. Thus, h_2 = 29.5 kJ/kg$_{da}$ and W_2 = 7.66 g$_w$/kg$_{da}$. From Table 3, h_{w2} = 42.02 kJ/kg$_w$. The mass flow of dry air is

$$\dot{m}_{da} = 5/0.877 = 5.70 \text{ kg}_{da}/\text{s}$$

From Equation (43),

$$_1q_2 = 5.70[(64.3 - 29.5) - (0.0133 - 0.00766)42.02]$$
$$= 197 \text{ kW}$$

Adiabatic Mixing of Two Moist Airstreams

A common process in air-conditioning systems is the adiabatic mixing of two moist airstreams. Figure 6 schematically shows the problem. Adiabatic mixing is governed by three equations:

$$\dot{m}_{da1}h_1 + \dot{m}_{da2}h_2 = \dot{m}_{da3}h_3$$
$$\dot{m}_{da1} + \dot{m}_{da2} = \dot{m}_{da3}$$
$$\dot{m}_{da1}W_1 + \dot{m}_{da2}W_2 = \dot{m}_{da3}W_3$$

Eliminating $\dot{m}_{da3}$ gives

$$\frac{h_2 - h_3}{h_3 - h_1} = \frac{W_2 - W_3}{W_3 - W_1} = \frac{\dot{m}_{da1}}{\dot{m}_{da2}} \quad (44)$$

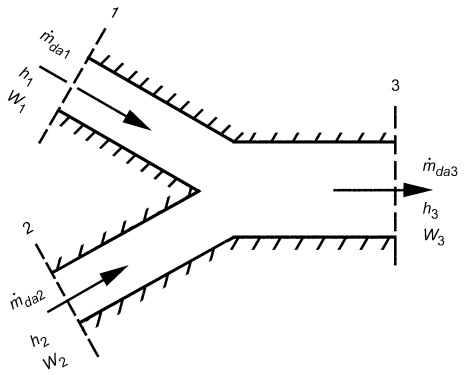

Fig. 6 Adiabatic Mixing of Two Moist Airstreams

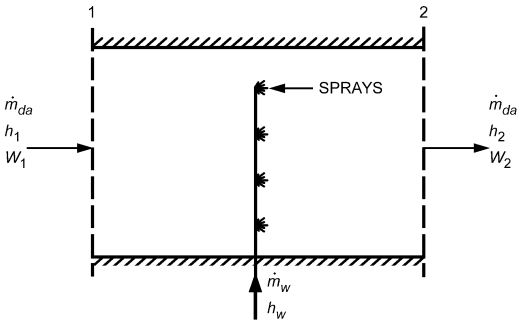

Fig. 8 Schematic Showing Injection of Water into Moist Air

according to which, on the ASHRAE chart, the state point of the resulting mixture lies on the straight line connecting the state points of the two streams being mixed, and divides the line into two segments, in the same ratio as the masses of dry air in the two streams.

Example 4. A stream of 2 m^3/s of outdoor air at 4°C dry-bulb temperature and 2°C thermodynamic wet-bulb temperature is adiabatically mixed with 6.25 m^3/s of recirculated air at 25°C dry-bulb temperature and 50% rh. Find the dry-bulb temperature and thermodynamic wet-bulb temperature of the resulting mixture.

Solution: Figure 7 shows the schematic solution. States 1 and 2 are located on the ASHRAE chart: v_1 = 0.789 m^3/kg$_{da}$, and v_2 = 0.858 m^3/kg$_{da}$. Therefore,

$$\dot{m}_{da1} = 2/0.789 = 2.535 \text{ kg}_{da}/\text{s}$$

$$\dot{m}_{da2} = 6.25/0.858 = 7.284 \text{ kg}_{da}/\text{s}$$

According to Equation (44),

$$\frac{\text{Line 3–2}}{\text{Line 1–3}} = \frac{\dot{m}_{da1}}{\dot{m}_{da2}} \text{ or } \frac{\text{Line 1–3}}{\text{Line 1–2}} = \frac{\dot{m}_{da2}}{\dot{m}_{da3}} = \frac{7.284}{9.819} = 0.742$$

Consequently, the length of line segment 1-3 is 0.742 times the length of entire line 1-2. Using a ruler, state 3 is located, and the values t_3 = 19.5°C and t_3^* = 14.6°C found.

Adiabatic Mixing of Water Injected into Moist Air

Steam or liquid water can be injected into a moist airstream to raise its humidity, as shown in Figure 8. If mixing is adiabatic, the following equations apply:

$$\dot{m}_{da}h_1 + \dot{m}_w h_w = \dot{m}_{da}h_2$$
$$\dot{m}_{da}W_1 + \dot{m}_w = \dot{m}_{da}W_2$$

Licensed for single user. © 2021 ASHRAE, Inc.

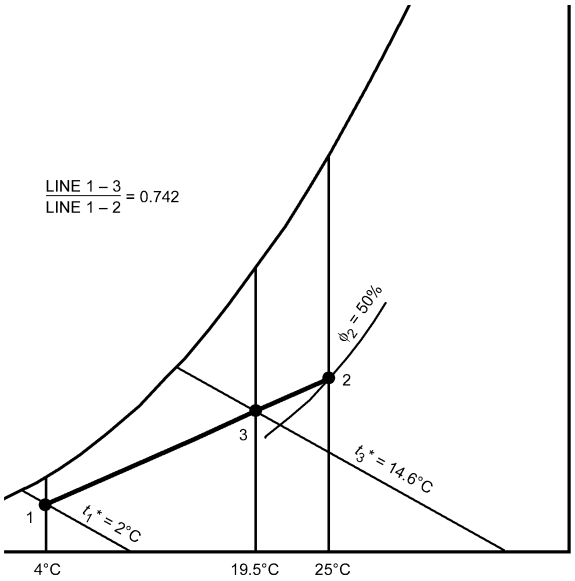

Fig. 7 Schematic Solution for Example 4

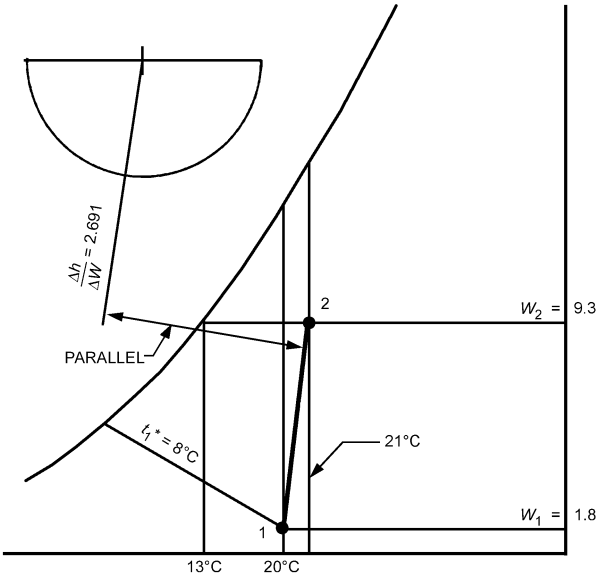

Fig. 9 Schematic Solution for Example 5

Therefore,

$$\frac{h_2 - h_1}{W_2 - W_1} = \frac{\Delta h}{\Delta W} = h_w \tag{45}$$

according to which, on the ASHRAE chart, the final state point of the moist air lies on a straight line in the direction fixed by the specific enthalpy of the injected water, drawn through the initial state point of the moist air.

Example 5. Moist air at 20°C dry-bulb and 8°C thermodynamic wet-bulb temperature is to be processed to a final dew-point temperature of 13°C by adiabatic injection of saturated steam at 110°C. The rate of dry airflow $\dot{m}_{da}$ is 2 kg_{da}/s. Find the final dry-bulb temperature of the moist air and the rate of steam flow.

Solution: Figure 9 shows the schematic solution. By Table 3, the enthalpy of the steam h_g = 2691.07 kJ/kg_w. Therefore, according to

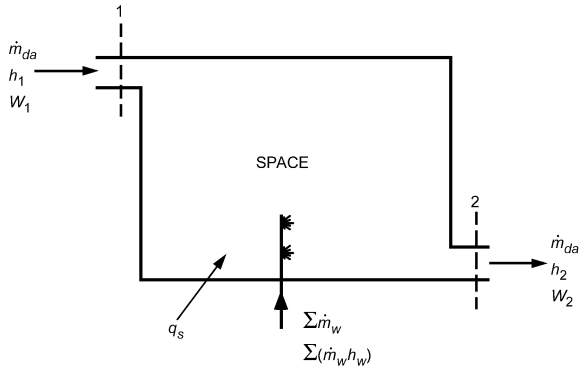

Fig. 10 Schematic of Air Conditioned Space

Equation (45), the condition line on the ASHRAE chart connecting states 1 and 2 must have a direction:

$$\Delta h/\Delta W = 2.691 \text{ kJ/g}_w$$

The condition line can be drawn with the $\Delta h/\Delta W$ protractor. First, establish the reference line on the protractor by connecting the origin with the value $\Delta h/\Delta W$ = 2.691 kJ/g_w. Draw a second line parallel to the reference line and through the initial state point of the moist air. This second line is the condition line. State 2 is established at the intersection of the condition line with the horizontal line extended from the saturation curve at 13°C (t_{d2} = 13°C). Thus, t_2 = 21°C.

Values of W_2 and W_1 can be read from the chart. The required steam flow is

$$\dot{m}_w = \dot{m}_{da}(W_2 - W_1) = 2 \times 1000(0.0093 - 0.0018)$$
$$= 15.0 \text{ g}_w\text{/s, or } 0.015 \text{ kg}_w\text{/s}$$

Space Heat Absorption and Moist Air Moisture Gains

Air conditioning required for a space is usually determined by (1) the quantity of moist air to be supplied, and (2) the supply air condition necessary to remove given amounts of energy and water from the space at the exhaust condition specified.

Figure 10 shows a space with incident rates of energy and moisture gains. The quantity q_s denotes the net sum of all rates of heat gain in the space, arising from transfers through boundaries and from sources within the space. This heat gain involves energy addition alone and does not include energy contributions from water (or water vapor) addition. It is usually called the **sensible heat gain**. The quantity $\Sigma\dot{m}_w$ denotes the net sum of all rates of moisture gain on the space arising from transfers through boundaries and from sources within the space. Each kilogram of water vapor added to the space adds an amount of energy equal to its specific enthalpy.

Assuming steady-state conditions, governing equations are

$$\dot{m}_{da}h_1 + q_s + \sum(\dot{m}_w h_w) = \dot{m}_{da}h_2$$

$$\dot{m}_{da}W_1 + \sum\dot{m}_w = \dot{m}_{da}W_2$$

or

$$q_s + \sum(\dot{m}_w h_w) = \dot{m}_{da}(h_2 - h_1) \tag{46}$$

$$\sum\dot{m}_w = \dot{m}_{da}(W_2 - W_1) \tag{47}$$

Licensed for single user. © 2021 ASHRAE, Inc.

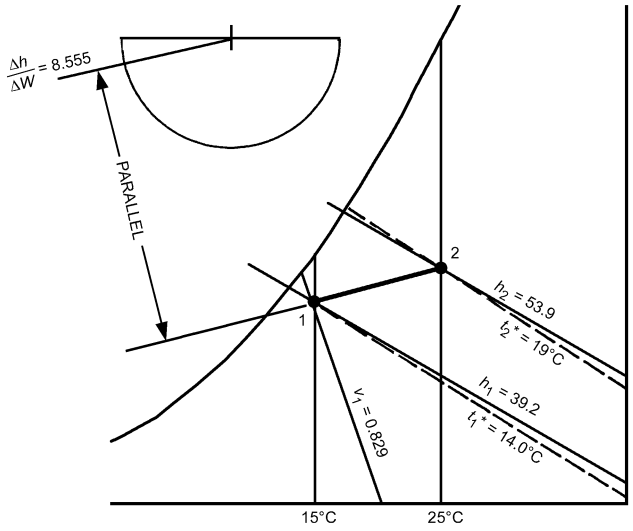

Fig. 11 Schematic Solution for Example 6

The left side of Equation (46) represents the total rate of energy addition to the space from all sources. By Equations (46) and (47),

$$\frac{h_2 - h_1}{W_2 - W_1} = \frac{\Delta h}{\Delta W} = \frac{q_s + \sum(\dot{m}_w h_w)}{\sum \dot{m}_w} \tag{48}$$

according to which, on the ASHRAE chart and for a given state of withdrawn air, all possible states (conditions) for supply air must lie on a straight line drawn through the state point of withdrawn air, with its direction specified by the numerical value of $[q_s + \Sigma(\dot{m}_w h_w)]/\Sigma\dot{m}_w$. This line is the condition line for the given problem.

Example 6. Moist air is withdrawn from a room at 25°C dry-bulb temperature and 19°C thermodynamic wet-bulb temperature. The sensible rate of heat gain for the space is 9 kW. A rate of moisture gain of 0.0015 kg_w/s occurs from the space occupants. This moisture is assumed as saturated water vapor at 30°C. Moist air is introduced into the room at a dry-bulb temperature of 15°C. Find the required thermodynamic wet-bulb temperature and volume flow rate of the supply air.

Solution: Figure 11 shows the schematic solution. State 2 is located on the ASHRAE chart. From Table 3, the specific enthalpy of the added water vapor is $h_g = 2555.58$ kJ/kg_w. From Equation (48),

$$\frac{\Delta h}{\Delta W} = \frac{9 + (0.0015 \times 2555.58)}{0.0015} = 8555 \text{ kJ/kg}_w$$

With the $\Delta h/\Delta W$ protractor, establish a reference line of direction $\Delta h/\Delta W = 8.555$ kJ/g_w. Parallel to this reference line, draw a straight line on the chart through state 2. The intersection of this line with the 15°C dry-bulb temperature line is state 1. Thus, $t_1^* = 14.0$°C.

An alternative (and approximately correct) procedure in establishing the condition line is to use the protractor's sensible/total heat ratio scale instead of the $\Delta h/\Delta W$ scale. The quantity $\Delta H_s/\Delta H_t$ is the ratio of rate of sensible heat gain for the space to rate of total energy gain for the space. Therefore,

$$\frac{\Delta H_s}{\Delta H_t} = \frac{q_s}{q_s + \Sigma(\dot{m}_w h_w)} = \frac{9}{9 + (0.0015 \times 2555.58)} = 0.701$$

Note that $\Delta H_s/\Delta H_t = 0.701$ on the protractor coincides closely with $\Delta h/\Delta W = 8.555$ kJ/g_w.

The flow of dry air can be calculated from either Equation (46) or (47). From Equation (46),

$$\dot{m}_{da} = \frac{q_s + \Sigma(\dot{m}_w h_w)}{h_2 - h_1} = \frac{9 + (0.0015 \times 2555.58)}{53.9 - 39.2}$$
$$= 0.873 \text{ kg/s}$$

At state 1, $v_1 = 0.829$ m^3/kg_{da}.

Therefore, supply volume $= \dot{m}_{da} v_1 = 0.873 \times 0.829 = 0.724$ m^3/s.

11. TRANSPORT PROPERTIES OF MOIST AIR

For certain scientific and experimental work, particularly in the heat transfer field, many other moist air properties are important. Generally classified as transport properties, these include diffusion coefficient, viscosity, thermal conductivity, and thermal diffusion factor. Mason and Monchick (1965) derive these properties by calculation. Table 4 and Figures 12 and 13 summarize the authors' results on the first three properties listed. Note that, within the boundaries of ASHRAE psychrometric charts 1, 2, and 3, viscosity varies little from that of dry air at normal atmospheric pressure, and thermal conductivity is essentially independent of moisture content.

Table 4 Calculated Diffusion Coefficients for Water/Air at 101.325 kPa

Temp., °C	mm^2/s	Temp., °C	mm^2/s	Temp., °C	mm^2/s
–70	13.2	0	22.2	50	29.5
–50	15.6	5	22.9	55	30.3
–40	16.9	10	23.6	60	31.1
–35	17.5	15	24.3	70	32.7
–30	18.2	20	25.1	100	37.6
–25	18.8	25	25.8	130	42.8

–5	21.5	45	28.8	250	66.3

12. SYMBOLS

C_1 to C_{18} = constants in Equations (5), (6), and (37)
d_v = absolute humidity of moist air, mass of water per unit volume of mixture, kg_w/m^3
h = specific enthalpy of moist air, kJ/kg_{da}
H_s = rate of sensible heat gain for space, kW
h_s^* = specific enthalpy of saturated moist air at thermodynamic wet-bulb temperature, kJ/kg_{da}
H_t = rate of total energy gain for space, kW
h_w^* = specific enthalpy of condensed water (liquid or solid) at thermodynamic wet-bulb temperature and a pressure of 101.325 kPa, kJ/kg_w
M_{da} = mass of dry air in moist air sample, kg_{da}
$\dot{m}_{da}$ = mass flow of dry air, per unit time, kg_{da}/s
M_w = mass of water vapor in moist air sample, kg_w
$\dot{m}_w$ = mass flow of water (any phase), per unit time, kg_w/s
n = $n_{da} + n_w$, total number of moles in moist air sample
n_{da} = moles of dry air
n_w = moles of water vapor
p = total pressure of moist air, kPa
p_{da} = partial pressure of dry air, kPa
p_s = vapor pressure of water in moist air at saturation, kPa. Differs slightly from saturation pressure of pure water because of presence of air.
p_w = partial pressure of water vapor in moist air, kPa
p_{ws} = pressure of saturated pure water, kPa
q_s = rate of addition (or withdrawal) of sensible heat, kW

R = universal gas constant, 8314.472 J/(kg mole·K)
R_{da} = gas constant for dry air, kJ/(kg$_{da}$·K)
R_w = gas constant for water vapor, kJ/(kg$_w$·K)
s = specific entropy, kJ/(kg$_{da}$·K) or kJ/(kg$_w$·K)
T = absolute temperature, K
t = dry-bulb temperature of moist air, °C
t_d = dew-point temperature of moist air, °C
t^* = thermodynamic wet-bulb temperature of moist air, °C
V = total volume of moist air sample, m^3
v = specific volume, m^3/kg$_{da}$ or m^3/kg$_w$
v_T = total gas volume, m^3
W = humidity ratio of moist air, kg$_w$/kg$_{da}$ or g$_w$/kg$_{da}$
W_s^* = humidity ratio of moist air at saturation at thermodynamic wet-bulb temperature, kg$_w$/kg$_{da}$ or g$_w$/kg$_{da}$
x_{da} = mole fraction of dry air, moles of dry air per mole of mixture
x_w = mole fraction of water, moles of water per mole of mixture
x_{ws} = mole fraction of water vapor under saturated conditions, moles of vapor per mole of saturated mixture
Z = altitude, m

Greek

α = $\ln(p_w)$, parameter used in Equations (37) and (38)
γ = specific humidity of moist air, mass of water per unit mass of mixture
ρ = moist air density
ϕ = relative humidity, dimensionless

Subscripts

as = difference between saturated moist air and dry air
da = dry air
f = saturated liquid water
fg = difference between saturated liquid water and saturated water vapor
g = saturated water vapor
i = saturated ice
ig = difference between saturated ice and saturated water vapor
s = saturated moist air
t = total
w = water in any phase

THERMODYNAMICS is the study of energy, its transformations, and its relation to states of matter. This chapter covers the application of thermodynamics to refrigeration cycles. The first part reviews the first and second laws of thermodynamics and presents methods for calculating thermodynamic properties. The second and third parts address compression and absorption refrigeration cycles, two common methods of thermal energy transfer.

1. THERMODYNAMICS

A **thermodynamic system** is a region in space or a quantity of matter bounded by a closed surface. The surroundings include everything external to the system, and the system is separated from the surroundings by the system boundaries. These boundaries can be movable or fixed, real or imaginary.

Entropy and energy are important in any thermodynamic system. **Entropy** measures the molecular disorder of a system. The more mixed a system, the greater its entropy; an orderly or unmixed configuration is one of low entropy. **Energy** has the capacity for producing an effect and can be categorized into either stored or transient forms.

1.1 STORED ENERGY

Thermal (internal) energy is caused by the motion of molecules and/or intermolecular forces.

Potential energy (PE) is caused by attractive forces existing between molecules, or the elevation of the system.

$$PE = mgz \quad (1)$$

where

m = mass
g = local acceleration of gravity
z = elevation above horizontal reference plane

Kinetic energy (KE) is the energy caused by the velocity of molecules and is expressed as

$$KE = mV^2/2 \quad (2)$$

where V is the velocity of a fluid stream crossing the system boundary.

The preparation of the first and second parts of this chapter is assigned to TC 1.1, Thermodynamics and Psychrometrics. The third and fourth parts are assigned to TC 8.3, Absorption and Heat Operated Machines.

Chemical energy is caused by the arrangement of atoms composing the molecules.

Nuclear (atomic) energy derives from the cohesive forces holding protons and neutrons together as the atom's nucleus.

1.2 ENERGY IN TRANSITION

Heat *Q* is the mechanism that transfers energy across the boundaries of systems with differing temperatures, always toward the lower temperature. Heat is positive when energy is added to the system (see Figure 1).

Work is the mechanism that transfers energy across the boundaries of systems with differing pressures (or force of any kind), always toward the lower pressure. If the total effect produced in the system can be reduced to the raising of a weight, then nothing but work has crossed the boundary. Work is positive when energy is removed from the system (see Figure 1).

Mechanical or **shaft work *W*** is the energy delivered or absorbed by a mechanism, such as a turbine, air compressor, or internal combustion engine.

Flow work is energy carried into or transmitted across the system boundary because a pumping process occurs somewhere outside the system, causing fluid to enter the system. It can be more easily understood as the work done by the fluid just outside the system on the adjacent fluid entering the system to force or push it into the system. Flow work also occurs as fluid leaves the system.

$$\text{Flow work (per unit mass)} = pv \quad (3)$$

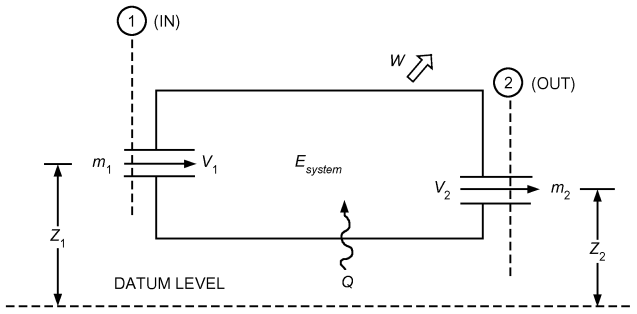

Fig. 1 Energy Flows in General Thermodynamic System

Copyright © 2021, ASHRAE

where p is pressure and v is specific volume, or the volume displaced per unit mass evaluated at the inlet or exit.

A **property** of a system is any observable characteristic of the system. The **state** of a system is defined by specifying the minimum set of independent properties. The most common thermodynamic properties are temperature T, pressure p, and specific volume v or density ρ. Additional thermodynamic properties include entropy, stored forms of energy, and enthalpy.

Frequently, thermodynamic properties combine to form other properties. **Enthalpy *h*** is an important property that includes internal energy and flow work and is defined as

$$h \equiv u + pv \tag{4}$$

where u is the internal energy per unit mass.

Each property in a given state has only one definite value, and any property always has the same value for a given state, regardless of how the substance arrived at that state.

A **process** is a change in state that can be defined as any change in the properties of a system. A process is described by specifying the initial and final equilibrium states, the path (if identifiable), and the interactions that take place across system boundaries during the process.

A **cycle** is a process or a series of processes wherein the initial and final states of the system are identical. Therefore, at the conclusion of a cycle, all the properties have the same value they had at the beginning. Refrigerant circulating in a closed system undergoes a cycle.

A **pure substance** has a homogeneous and invariable chemical composition. It can exist in more than one phase, but the chemical composition is the same in all phases.

If a substance is liquid at the saturation temperature and pressure, it is called a **saturated liquid**. If the temperature of the liquid is lower than the saturation temperature for the existing pressure, it is called either a **subcooled liquid** (the temperature is lower than the saturation temperature for the given pressure) or a **compressed liquid** (the pressure is greater than the saturation pressure for the given temperature).

When a substance exists as part liquid and part vapor at the saturation temperature, its **quality** is defined as the ratio of the mass of vapor to the total mass. Quality has meaning only when the substance is saturated (i.e., at saturation pressure and temperature). Pressure and temperature of saturated substances are not independent properties.

If a substance exists as a vapor at saturation temperature and pressure, it is called a **saturated vapor**. (Sometimes the term **dry saturated vapor** is used to emphasize that the quality is 100%.) When the vapor is at a temperature greater than the saturation temperature, it is a **superheated vapor**. Pressure and temperature of a superheated vapor are independent properties, because the temperature can increase while pressure remains constant. Gases such as air at room temperature and pressure are highly superheated vapors.

1.3 FIRST LAW OF THERMODYNAMICS

The first law of thermodynamics is often called the **law of conservation of energy**. The following form of the first-law equation is valid only in the absence of a nuclear or chemical reaction.

Based on the first law or the law of conservation of energy, for any system, open or closed, there is an energy balance as

$$\left[\begin{array}{c}\text{Net amount of energy}\\ \text{added to system}\end{array}\right] = \left[\begin{array}{c}\text{Net increase of stored}\\ \text{energy in system}\end{array}\right]$$

or

[Energy in] – [Energy out] = [Increase of stored energy in system]

Figure 1 illustrates energy flows into and out of a thermodynamic system. For the general case of multiple mass flows with uniform properties in and out of the system, the energy balance can be written

$$\begin{aligned}&\sum m_{in}\left(u + pv + \frac{V^2}{2} + gz\right)_{in}\\ &- \sum m_{out}\left(u + pv + \frac{V^2}{2} + gz\right)_{out} + Q - W\\ &= \left[m_f\left(u + \frac{V^2}{2} + gz\right)_f - m_i\left(u + \frac{V^2}{2} + gz\right)_i\right]_{system}\end{aligned} \tag{5}$$

where subscripts i and f refer to the initial and final states, respectively.

Nearly all important engineering processes are commonly modeled as steady-flow processes. Steady flow signifies that all quantities associated with the system do not vary with time. Consequently,

$$\begin{aligned}&\sum_{\substack{\text{all streams}\\ \text{entering}}} m\left(h + \frac{V^2}{2} + gz\right)\\ &- \sum_{\substack{\text{all streams}\\ \text{leaving}}} m\left(h + \frac{V^2}{2} + gz\right) + Q - W = 0\end{aligned} \tag{6}$$

where $h \equiv u + pv$ as described in Equation (4).

A second common application is the closed stationary system for which the first law equation reduces to

$$Q - W = [m(u_f - u_i)]_{system} \tag{7}$$

1.4 SECOND LAW OF THERMODYNAMICS

The second law of thermodynamics differentiates and quantifies processes that only proceed in a certain direction (irreversible) from those that are reversible. The second law may be described in several ways. One method uses the concept of entropy flow in an open system and the irreversibility associated with the process. The concept of irreversibility provides added insight into the operation of cycles. For example, the larger the irreversibility in a refrigeration cycle operating with a given refrigeration load between two fixed temperature levels, the larger the amount of work required to operate the cycle. Irreversibilities include pressure drops in lines and heat exchangers, heat transfer between fluids of different temperature, and mechanical friction. Reducing total irreversibility in a cycle improves cycle performance. In the limit of no irreversibilities, a cycle attains its maximum ideal efficiency.

In an open system, the second law of thermodynamics can be described in terms of entropy as

$$dS_{system} = \frac{\delta Q}{T} + \delta m_i s_i - \delta m_e s_e + dI \tag{8}$$

where

dS_{system} = total change within system in time dt during process
$\delta m_i s_i$ = entropy increase caused by mass entering (incoming)
$\delta m_e s_e$ = entropy decrease caused by mass leaving (exiting)
$\delta Q/T$ = entropy change caused by reversible heat transfer between system and surroundings at temperature T
dI = entropy caused by irreversibilities (always positive)

Equation (8) accounts for all entropy changes in the system. Rearranged, this equation becomes

$$\delta Q = T[(\delta m_e s_e - \delta m_i s_i) + dS_{sys} - dI] \tag{9}$$

Licensed for single user. © 2021 ASHRAE, Inc.

In integrated form, if inlet and outlet properties, mass flow, and interactions with the surroundings do not vary with time, the general equation for the second law is

$$(S_f - S_i)_{system} = \int_{rev} \frac{\delta Q}{T} + \sum (ms)_{in} - \sum (ms)_{out} + I \qquad (10)$$

In many applications, the process can be considered to operate steadily with no change in time. The change in entropy of the system is therefore zero. The **irreversibility rate**, which is the rate of entropy production caused by irreversibilities in the process, can be determined by rearranging Equation (10):

$$I = \sum (ms)_{out} - \sum (ms)_{in} - \sum \frac{Q}{T_{surr}} \qquad (11)$$

Equation (6) can be used to replace the heat transfer quantity. Note that the absolute temperature of the surroundings with which the system is exchanging heat is used in the last term. If the temperature of the surroundings is equal to the system temperature, heat is transferred reversibly and the last term in Equation (11) equals zero.

Equation (11) is commonly applied to a system with one mass flow in, the same mass flow out, no work, and negligible kinetic or potential energy flows. Combining Equations (6) and (11) yields

$$I = m\left[(s_{out} - s_{in}) - \frac{h_{out} - h_{in}}{T_{surr}}\right] \qquad (12)$$

In a cycle, the reduction of work produced by a power cycle (or the increase in work required by a refrigeration cycle) equals the absolute ambient temperature multiplied by the sum of irreversibilities in all processes in the cycle. Thus, the difference in reversible and actual work for any refrigeration cycle, theoretical or real, operating under the same conditions, becomes

$$W_{actual} = W_{reversible} + T_0 \sum I \qquad (13)$$

Another second-law method to describe performance of engineering devices is the concept of **exergy** (also called the *availability*, *potential energy*, or *work potential*), which is the maximum useful work that could be obtained from the system at a given state in a specified environment. There is always a difference between exergy and the actual work delivered by a device; this difference represents the room for improvement. Note that exergy is a property of the system/environment combination and not of the system alone. The exergy of a system in equilibrium with its environment is zero. The state of the environment is referred to as the **dead state**, because the system cannot do any work.

Exergy transfer is in three forms (heat, work, and mass flow), and is given by

$$X_{heat} = \left(1 - \frac{T_0}{T}\right) Q$$

$$X_{work} = \begin{cases} W - W_{surr} & \text{(for boundary work)} \\ W & \text{(for other forms of work)} \end{cases}$$

$$X_{mass} = m\psi$$

where $\psi = (h - h_0) - T_0(s - s_0) + (V^2/2) + gz$ is flow exergy.

Exergy balance for any system undergoing any process can be expressed as

$$\underbrace{X_{in} - X_{out}}_{\text{Net exergy transfer by heat, work, and mass}} - \underbrace{X_{destroyed}}_{\text{Exergy destruction}} = \underbrace{\Delta X_{system}}_{\text{Change in exergy}} \quad \text{(general)}$$

$$\underbrace{X_{in} - X_{out}}_{\text{Rate of net exergy transfer by heat, work, and mass}} - \underbrace{X_{destroyed}}_{\text{Rate of exergy destruction}} = \underbrace{dX_{system}/dt}_{\text{Rate of change in exergy}} \quad \text{(general, in rate form)}$$

Taking the positive direction of heat transfer as *to* the system and the positive direction of work transfer as *from* the system, the general exergy balance relations can be expressed explicitly as

$$\sum \left(1 - \frac{T_0}{T_k}\right) Q_k - [W - P_0(V_2 - V_1)] + \sum_{in} m\psi - \sum_{out} m\psi - X_{destroyed} = X_2 - X_1$$

1.5 THERMODYNAMIC ANALYSIS OF REFRIGERATION CYCLES

Refrigeration cycles transfer thermal energy from a region of low temperature T_R to one of higher temperature. Usually the higher-temperature heat sink is the ambient air or cooling water, at temperature T_0, the temperature of the surroundings.

The first and second laws of thermodynamics can be applied to individual components to determine mass and energy balances and the irreversibility of the components. This procedure is shown in later sections in this chapter.

Performance of a refrigeration cycle is usually described by a **coefficient of performance (COP)**, defined as the benefit of the cycle (amount of heat removed) divided by the required energy input to operate the cycle:

$$\text{COP} \equiv \frac{\text{Useful refrigerating effect}}{\text{Net energy supplied from external sources}} \qquad (14)$$

For a mechanical vapor compression system, the net energy supplied is usually in the form of work, mechanical or electrical, and may include work to the compressor and fans or pumps. Thus,

$$\text{COP} = \frac{Q_{evap}}{W_{net}} \qquad (15)$$

In an absorption refrigeration cycle, the net energy supplied is usually in the form of heat into the generator and work into the pumps and fans, or

$$\text{COP} = \frac{Q_{evap}}{Q_{gen} + W_{net}} \qquad (16)$$

In many cases, work supplied to an absorption system is very small compared to the amount of heat supplied to the generator, so the work term is often neglected.

Applying the second law to an entire refrigeration cycle shows that a completely reversible cycle operating under the same conditions has the maximum possible COP. Departure of the actual cycle from an ideal reversible cycle is given by the **refrigerating efficiency**:

$$\eta_R = \frac{\text{COP}}{(\text{COP})_{rev}} \qquad (17)$$

The Carnot cycle usually serves as the ideal reversible refrigeration cycle. For multistage cycles, each stage is described by a reversible cycle.

1.6 EQUATIONS OF STATE

The equation of state of a pure substance is a mathematical relation between pressure, specific volume, and temperature. When the system is in thermodynamic equilibrium,

$$f(p,v,T) = 0 \tag{18}$$

The principles of statistical mechanics are used to (1) explore the fundamental properties of matter, (2) predict an equation of state based on the statistical nature of a particular system, or (3) propose a functional form for an equation of state with unknown parameters that are determined by measuring thermodynamic properties of a substance. A fundamental equation with this basis is the **virial equation**, which is expressed as an expansion in pressure p or in reciprocal values of volume per unit mass v as

$$\frac{pv}{RT} = 1 + B'p + C'p^2 + D'p^3 + \cdots \tag{19}$$

$$\frac{pv}{RT} = 1 + (B/v) + (C/v^2) + (D/v^3) + \cdots \tag{20}$$

where coefficients B', C', D', etc., and B, C, D, etc., are the virial coefficients. B' and B are the second virial coefficients; C' and C are the third virial coefficients, etc. The virial coefficients are functions of temperature only, and values of the respective coefficients in Equations (19) and (20) are related. For example, $B' = B/RT$ and $C' = (C - B^2)/(RT)^2$.

The universal gas constant $\mathcal{R}$ is defined as

$$\mathcal{R} = \lim_{p \to 0} \frac{(p\mathfrak{v})_T}{T} \tag{21}$$

where $(p\mathfrak{v})_T$ is the product of the pressure and the molar specific volume along an isotherm with absolute temperature T. The current best value of $\mathcal{R}$ is 8314.41 J/(kg mol·K). The gas constant R is equal to the universal gas constant $\mathcal{R}$ divided by the molecular mass M of the gas or gas mixture.

The quantity pv/RT is also called the **compressibility factor** Z, or

$$Z = 1 + (B/v) + (C/v^2) + (D/v^3) + \cdots \tag{22}$$

An advantage of the virial form is that statistical mechanics can be used to predict the lower-order coefficients and provide physical significance to the virial coefficients. For example, in Equation (22), the term B/v is a function of interactions between two molecules, C/v^2 between three molecules, etc. Because lower-order interactions are common, contributions of the higher-order terms are successively less. Thermodynamicists use the partition or distribution function to determine virial coefficients; however, experimental values of the second and third coefficients are preferred. For dense fluids, many higher-order terms are necessary that can neither be satisfactorily predicted from theory nor determined from experimental measurements. In general, a truncated virial expansion of four terms is valid for densities of less than one-half the value at the critical point. For higher densities, additional terms can be used and determined empirically.

Computers allow the use of very complex equations of state in calculating p-v-T values, even to high densities. The Benedict-Webb-Rubin (B-W-R) equation of state (Benedict et al. 1940) and Martin-Hou equation (1955) have had considerable use, but should generally be limited to densities less than the critical value. Strobridge (1962) suggested a modified Benedict-Webb-Rubin relation that gives excellent results at higher densities and can be used for a p-v-T surface that extends into the liquid phase.

The B-W-R equation has been used extensively for hydrocarbons (Cooper and Goldfrank 1967):

$$P = (RT/v) + (B_oRT - A_o - C_o/T^2)/v^2 + (bRT - a)/v^3 + (a\alpha)/v^6 + [c(1 + \gamma/v^2)e^{(-\gamma/v^2)}]/v^3T^2 \tag{23}$$

where the constant coefficients are A_o, B_o, C_o, a, b, c, α, and γ.

The Martin-Hou equation, developed for fluorinated hydrocarbon properties, has been used to calculate the thermodynamic property tables in Chapter 30 and in *ASHRAE Thermodynamic Properties of Refrigerants* (Stewart et al. 1986). The Martin-Hou equation is

$$p = \frac{RT}{v-b} + \frac{A_2 + B_2T + C_2e^{(-kT/T_c)}}{(v-b)^2} + \frac{A_3 + B_3T + C_3e^{(-kT/T_c)}}{(v-b)^3} + \frac{A_4 + B_4T}{(v-b)^4} + \frac{A_5 + B_5T + C_5e^{(-kT/T_c)}}{(v-b)^5} + (A_6 + B_6T)e^{av} \tag{24}$$

where the constant coefficients are A_i, B_i, C_i, k, b, and a.

Strobridge (1962) suggested an equation of state that was developed for nitrogen properties and used for most cryogenic fluids. This equation combines the B-W-R equation of state with an equation for high-density nitrogen suggested by Benedict (1937). These equations have been used successfully for liquid and vapor phases, extending in the liquid phase to the triple-point temperature and the freezing line, and in the vapor phase from 10 to 1000 K, with pressures to 1 GPa. The Strobridge equation is accurate within the uncertainty of the measured p-v-T data:

$$p = RT\rho + \left[Rn_1T + n_2 + \frac{n_3}{T} + \frac{n_4}{T^2} + \frac{n_5}{T^4}\right]\rho^2 + (Rn_6T + n_7)\rho^3 + n_8T\rho^4 + \rho^3\left[\frac{n_9}{T^2} + \frac{n_{10}}{T^3} + \frac{n_{11}}{T^4}\right]\exp(-n_{16}\rho^2) + \rho^5\left[\frac{n_{12}}{T^2} + \frac{n_{13}}{T^3} + \frac{n_{14}}{T^4}\right]\exp(-n_{16}\rho^2) + n_{15}\rho^6 \tag{25}$$

The 15 coefficients of this equation's linear terms are determined by a least-square fit to experimental data. Hust and McCarty (1967) and Hust and Stewart (1966) give further information on methods and techniques for determining equations of state.

In the absence of experimental data, van der Waals' principle of corresponding states can predict fluid properties. This principle relates properties of similar substances by suitable reducing factors (i.e., the p-v-T surfaces of similar fluids in a given region are assumed to be of similar shape). The critical point can be used to define reducing parameters to scale the surface of one fluid to the dimensions of another. Modifications of this principle, as suggested by Kamerlingh Onnes, a Dutch cryogenic researcher, have been used to improve correspondence at low pressures. The principle of corresponding states provides useful approximations, and numerous modifications have been reported. More complex treatments for predicting properties, which recognize similarity of fluid properties, are by generalized equations of state. These equations ordinarily allow adjustment of the p-v-T surface by introducing parameters. One example (Hirschfelder et al. 1958) allows for departures from the principle of corresponding states by adding two correlating parameters.

1.7 CALCULATING THERMODYNAMIC PROPERTIES

Although equations of state provide p-v-T relations, thermodynamic analysis usually requires values for internal energy,

Licensed for single user. © 2021 ASHRAE, Inc.

enthalpy, and entropy. These properties have been tabulated for many substances, including refrigerants (see Chapters 1, 30, and 33), and can be extracted from such tables by interpolating manually or with a suitable computer program. This approach is appropriate for hand calculations and for relatively simple computer models; however, for many computer simulations, the overhead in memory or input and output required to use tabulated data can make this approach unacceptable. For large thermal system simulations or complex analyses, it may be more efficient to determine internal energy, enthalpy, and entropy using fundamental thermodynamic relations or curves fit to experimental data. Some of these relations are discussed in the following sections. Also, the thermodynamic relations discussed in those sections are the basis for constructing tables of thermodynamic property data. Further information on the topic may be found in references covering system modeling and thermodynamics (Howell and Buckius 1992; Stoecker 1989).

At least two intensive properties (properties independent of the quantity of substance, such as temperature, pressure, specific volume, and specific enthalpy) must be known to determine the remaining properties. If two known properties are either p, v, or T (these are relatively easy to measure and are commonly used in simulations), the third can be determined throughout the range of interest using an equation of state. Furthermore, if the specific heats at zero pressure are known, specific heat can be accurately determined from spectroscopic measurements using statistical mechanics (NASA 1971). Entropy may be considered a function of T and p, and from calculus an infinitesimal change in entropy can be written as

$$ds = \left(\frac{\partial s}{\partial T}\right)_p dT + \left(\frac{\partial s}{\partial p}\right)_T dp \tag{26}$$

Likewise, a change in enthalpy can be written as

$$dh = \left(\frac{\partial h}{\partial T}\right)_p dT + \left(\frac{\partial h}{\partial p}\right)_T dp \tag{27}$$

Using the Gibbs relation $Tds = dh - vdp$ and the definition of specific heat at constant pressure, $c_p \equiv (\partial h/\partial T)_p$, Equation (27) can be rearranged to yield

$$ds = \frac{c_p}{T}dT + \left[\left(\frac{\partial h}{\partial p}\right)_T - v\right]\frac{dp}{T} \tag{28}$$

Equations (26) and (28) combine to yield $(\partial s/\partial T)_p = c_p/T$. Then, using the Maxwell relation $(\partial s/\partial p)_T = -(\partial v/\partial T)_p$, Equation (26) may be rewritten as

$$ds = \frac{c_p}{T}dT - \left(\frac{\partial v}{\partial T}\right)_p dp \tag{29}$$

This is an expression for an exact derivative, so it follows that

$$\left(\frac{\partial c_p}{\partial p}\right)_T = -T\left(\frac{\partial^2 v}{\partial T^2}\right)_p \tag{30}$$

Integrating this expression at a fixed temperature yields

$$c_p = c_{p0} - \int_0^p T\left(\frac{\partial^2 v}{\partial T^2}\right) dp_T \tag{31}$$

where c_{p0} is the known zero-pressure specific heat, and dp_T is used to indicate that integration is performed at a fixed temperature. The second partial derivative of specific volume with respect to temperature can be determined from the equation of state. Thus, Equation (31) can be used to determine the specific heat at any pressure.

Using $Tds = dh - vdp$, Equation (29) can be written as

$$dh = c_p dT + \left[v - T\left(\frac{\partial v}{\partial T}\right)_p\right] dp \tag{32}$$

Equations (28) and (32) may be integrated at constant pressure to obtain

$$s(T_1, p_0) = s(T_0, p_0) + \int_{T_0}^{T_1} \frac{c_p}{T} dT_p \tag{33}$$

and

$$h(T_1, p_0) = h(T_0, p_0) + \int_{T_0}^{T_1} c_p dT \tag{34}$$

Integrating the Maxwell relation $(\partial s/\partial p)_T = -(\partial v/\partial T)_p$ gives an equation for entropy changes at a constant temperature as

$$s(T_0, p_1) = s(T_0, p_0) - \int_{p_0}^{p_1} \left(\frac{\partial v}{\partial T}\right)_p dp_T \tag{35}$$

Likewise, integrating Equation (32) along an isotherm yields the following equation for enthalpy changes at a constant temperature:

$$h(T_0, p_1) = h(T_0, p_0) + \int_{p_0}^{p_1} \left[v - T\left(\frac{\partial v}{\partial T}\right)_p\right] dp \tag{36}$$

Internal energy can be calculated from $u = h - pv$. When entropy or enthalpy are known at a reference temperature T_0 and pressure p_0, values at any temperature and pressure may be obtained by combining Equations (33) and (35) or Equations (34) and (36).

Combinations (or variations) of Equations (33) to (36) can be incorporated directly into computer subroutines to calculate properties with improved accuracy and efficiency. However, these equations are restricted to situations where the equation of state is valid and the properties vary continuously. These restrictions are violated by a change of phase such as evaporation and condensation, which are essential processes in air-conditioning and refrigerating devices. Therefore, the Clapeyron equation is of particular value; for evaporation or condensation, it gives

$$\left(\frac{dp}{dT}\right)_{sat} = \frac{s_{fg}}{v_{fg}} = \frac{h_{fg}}{Tv_{fg}} \tag{37}$$

where

s_{fg} = entropy of vaporization
h_{fg} = enthalpy of vaporization
v_{fg} = specific volume difference between vapor and liquid phases

If vapor pressure and liquid and vapor density data (all relatively easy measurements to obtain) are known at saturation, then changes in enthalpy and entropy can be calculated using Equation (37).

Phase Equilibria for Multicomponent Systems

To understand phase equilibria, consider a container full of a liquid made of two components; the more volatile component is designated i and the less volatile component j (Figure 2A). This mixture is all liquid because the temperature is low (but not so low that a solid appears). Heat added at a constant pressure raises the mixture's temperature, and a sufficient increase causes vapor to form, as shown in Figure 2B. If heat at constant pressure continues to be added, eventually the temperature becomes so high that only vapor remains in the container (Figure 2C). A temperature-concentration (T-x) diagram is useful for exploring details of this situation.

Figure 3 is a typical T-x diagram valid at a fixed pressure. The case shown in Figure 2A, a container full of liquid mixture with

Licensed for single user. © 2021 ASHRAE, Inc.

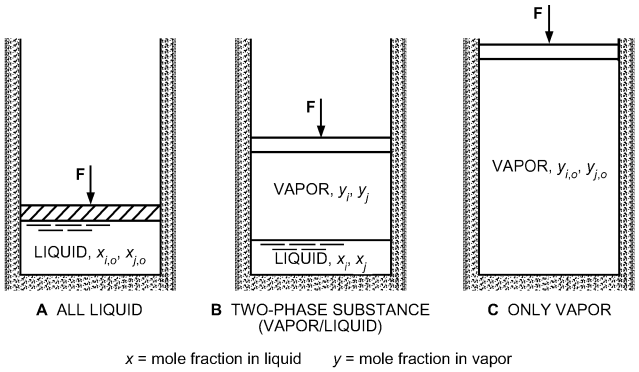

Fig. 2 Mixture of *i* and *j* Components in Constant-Pressure Container

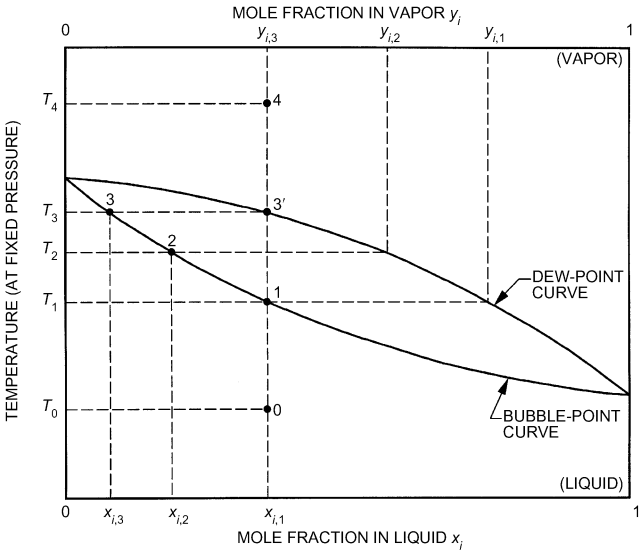

Fig. 3 Temperature-Concentration (*T*-*x*) Diagram for Zeotropic Mixture

mole fraction $x_{i,0}$ at temperature T_0, is point 0 on the T-x diagram. When heat is added, the mixture's temperature increases. The point at which vapor begins to form is the **bubble point**. Starting at point 0, the first bubble forms at temperature T_1 (point 1 on the diagram). The locus of bubble points is the **bubble-point curve**, which provides bubble points for various liquid mole fractions x_i.

When the first bubble begins to form, vapor in the bubble may not have the same mole fraction as the liquid mixture. Rather, the mole fraction of the more volatile species is higher in the vapor than in the liquid. Boiling prefers more volatile species, and the T-x diagram shows this behavior. At T_1, the vapor-forming bubbles have an i mole fraction of $y_{i,1}$. If heat continues to be added, this preferential boiling depletes the liquid of species i and the temperature required to continue the process increases. Again, the T-x diagram reflects this fact; at point 2 the i mole fraction in the liquid is reduced to $x_{i,2}$ and the vapor has a mole fraction of $y_{i,2}$. The temperature required to boil the mixture is increased to T_2. Position 2 on the T-x diagram could correspond to the physical situation shown in Figure 2B.

If constant-pressure heating continues, all the liquid eventually becomes vapor at temperature T_3. The vapor at this point is shown as position 3′ in Figure 3. At this point the i mole fraction in the vapor $y_{i,3}$ equals the starting mole fraction in the all-liquid mixture $x_{i,1}$. This equality is required for mass and species conservation.

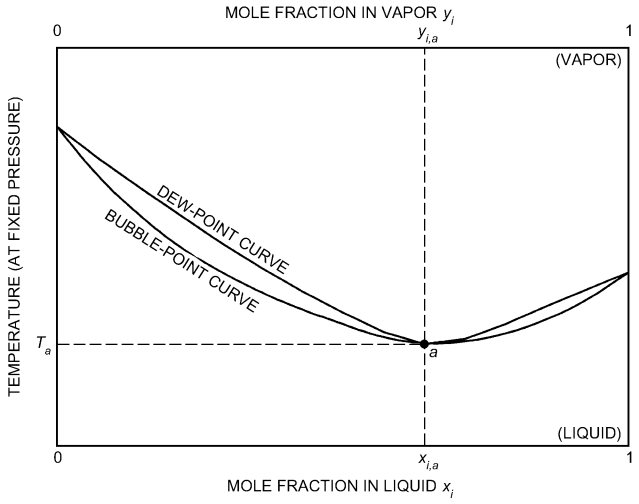

Fig. 4 Azeotropic Behavior Shown on *T*-*x* Diagram

Further addition of heat simply raises the vapor temperature. The final position 4 corresponds to the physical situation shown in Figure 2C.

Starting at position 4 in Figure 3, heat removal leads to initial liquid formation when position 3′ (the **dew point**) is reached. The locus of dew points is called the **dew-point curve**. Heat removal causes the liquid phase of the mixture to reverse through points 3, 2, 1, and to starting point 0. Because the composition shifts, the temperature required to boil (or condense) this mixture changes as the process proceeds. This is known as **temperature glide**. This mixture is therefore called **zeotropic**.

Most mixtures have T-x diagrams that behave in this fashion, but some have a markedly different feature. If the dew-point and bubble-point curves intersect at any point other than at their ends, the mixture exhibits **azeotropic** behavior at that composition. This case is shown as position a in the T-x diagram of Figure 4. If a container of liquid with a mole fraction x_a were boiled, vapor would be formed with an identical mole fraction y_a. The addition of heat at constant pressure would continue with no shift in composition and no temperature glide.

Perfect azeotropic behavior is uncommon, although near-azeotropic behavior is fairly common. The azeotropic composition is pressure dependent, so operating pressures should be considered for their effect on mixture behavior. Azeotropic and near-azeotropic refrigerant mixtures are widely used. The properties of an azeotropic mixture are such that they may be conveniently treated as pure substance properties. Phase equilibria for zeotropic mixtures, however, require special treatment, using an equation-of-state approach with appropriate mixing rules or using the fugacities with the standard state method (Tassios 1993). Refrigerant and lubricant blends are a zeotropic mixture and can be treated by these methods (Martz et al. 1996a, 1996b; Thome 1995).

2. COMPRESSION REFRIGERATION CYCLES

2.1 CARNOT CYCLE

The Carnot cycle, which is completely reversible, is a perfect model for a refrigeration cycle operating between two fixed temperatures, or between two fluids at different temperatures and each with infinite heat capacity. Reversible cycles have two important properties: (1) no refrigerating cycle may have a coefficient of performance higher than that for a reversible cycle operated between the same temperature limits, and (2) all reversible cycles, when

Licensed for single user. © 2021 ASHRAE, Inc.

operated between the same temperature limits, have the same coefficient of performance. Proof of both statements may be found in almost any textbook on elementary engineering thermodynamics.

Figure 5 shows the Carnot cycle on temperature-entropy coordinates. Heat is withdrawn at constant temperature T_R from the region to be refrigerated. Heat is rejected at constant ambient temperature T_0. The cycle is completed by an isentropic expansion and an isentropic compression. The energy transfers are given by

$$Q_0 = T_0(S_2 - S_3)$$
$$Q_i = T_R(S_1 - S_4) = T_R(S_2 - S_3)$$
$$W_{net} = Q_o - Q_i$$

Thus, by Equation (15),

$$\text{COP} = \frac{T_R}{T_0 - T_R} \tag{38}$$

Example 1. Determine entropy change, work, and COP for the cycle shown in Figure 6. Temperature of the refrigerated space T_R is 250 K, and that of the atmosphere T_0 is 300 K. Refrigeration load is 125 kJ.

Solution:

$$\Delta S = S_1 - S_4 = Q_i/T_R = 125/250 = 0.5 \text{ kJ/K}$$

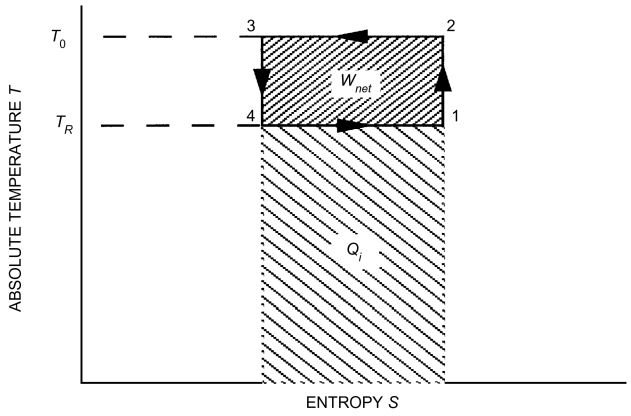

Fig. 5 Carnot Refrigeration Cycle

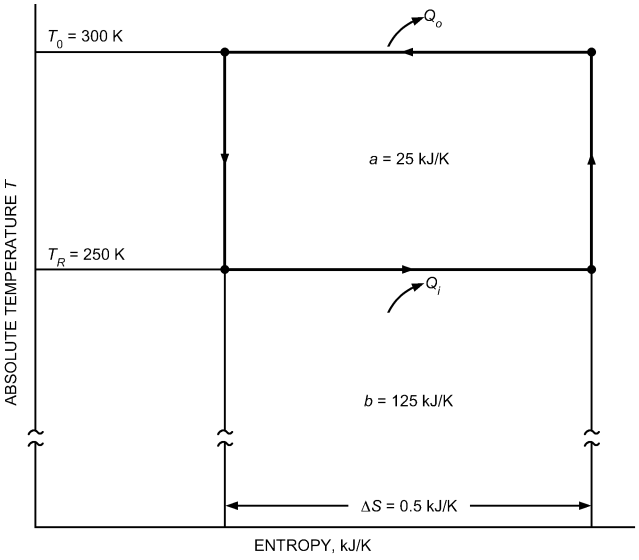

Fig. 6 Temperature-Entropy Diagram for Carnot Refrigeration Cycle of Example 1

$$W = \Delta S(T_0 - T_R) = 0.5(300 - 250) = 25 \text{ kJ}$$
$$\text{COP} = Q_i/(Q_o - Q_i) = Q_i/W = 125/25 = 5$$

Flow of energy and its area representation in Figure 6 are

Energy	kJ	Area
Q_i	125	b
Q_o	150	$a + b$
W	25	a

The net change of entropy of any refrigerant in any cycle is always zero. In Example 1, the change in entropy of the refrigerated space is $\Delta S_R = -125/250 = -0.5$ kJ/K and that of the atmosphere is $\Delta S_o = 125/250 = 0.5$ kJ/K. The net change in entropy of the isolated system is $\Delta S_{total} = \Delta S_R + \Delta S_o = 0$.

The Carnot cycle in Figure 7 shows a process in which heat is added and rejected at constant pressure in the two-phase region of a refrigerant. Saturated liquid at state 3 expands isentropically to the low temperature and pressure of the cycle at state d. Heat is added isothermally and isobarically by evaporating the liquid-phase refrigerant from state d to state 1. The cold saturated vapor at state 1 is compressed isentropically to the high temperature in the cycle at state b. However, the pressure at state b is below the saturation pressure corresponding to the high temperature in the cycle. The compression process is completed by an isothermal compression process from state b to state c. The cycle is completed by an isothermal and isobaric heat rejection or condensing process from state c to state 3.

Applying the energy equation for a mass of refrigerant m yields (all work and heat transfer are positive)

$$_3W_d = m(h_3 - h_d)$$
$$_1W_b = m(h_b - h_1)$$
$$_bW_c = T_0(S_b - S_c) - m(h_b - h_c)$$
$$_dQ_1 = m(h_1 - h_d) = \text{Area def1d}$$

The net work for the cycle is

$$W_{net} = {}_1W_b + {}_bW_c - {}_3W_d = \text{Area d1bc3d}$$

and

$$\text{COP} = \frac{{}_dQ_1}{W_{net}} = \frac{T_R}{T_0 - T_R}$$

2.2 THEORETICAL SINGLE-STAGE CYCLE USING A PURE REFRIGERANT OR AZEOTROPIC MIXTURE

A system designed to approach the ideal model shown in Figure 7 is desirable. A pure refrigerant or azeotropic mixture can be used to maintain constant temperature during phase changes by maintaining constant pressure. Because of concerns such as high initial cost and increased maintenance requirements, a practical machine

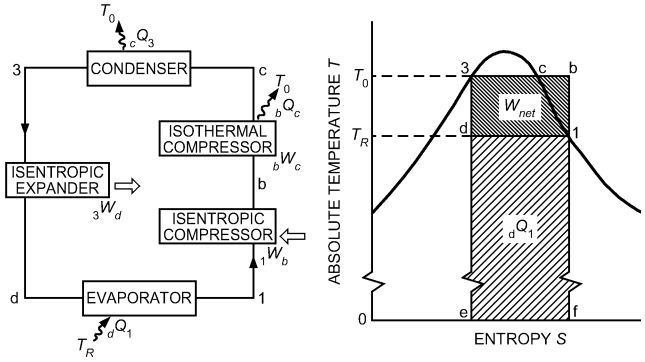

Fig. 7 Carnot Vapor Compression Cycle

Licensed for single user. © 2021 ASHRAE, Inc.

has one compressor instead of two and the expander (engine or turbine) is replaced by a simple expansion valve, which throttles refrigerant from high to low pressure. Figure 8 shows the theoretical single-stage cycle used as a model for actual systems.

Applying the energy equation for a mass m of refrigerant yields

$$ {}_4Q_1 = m(h_1 - h_4) \tag{39a} $$

$$ {}_1W_2 = m(h_2 - h_1) \tag{39b} $$

$$ {}_2Q_3 = m(h_2 - h_3) \tag{39c} $$

$$ h_3 = h_4 \tag{39d} $$

Constant-enthalpy throttling assumes no heat transfer or change in potential or kinetic energy through the expansion valve.

The coefficient of performance is

$$ \text{COP} = \frac{{}_4Q_1}{{}_1W_2} = \frac{h_1 - h_4}{h_2 - h_1} \tag{40} $$

The theoretical compressor displacement CD (at 100% volumetric efficiency) is

$$ \text{CD} = mv_1 \tag{41} $$

which is a measure of the physical size or speed of the compressor required to handle the prescribed refrigeration load.

Example 2. A theoretical single-stage cycle using R-134a as the refrigerant operates with a condensing temperature of 30°C and an evaporating temperature of –20°C. The system produces 50 kW of refrigeration. Determine the (a) thermodynamic property values at the four main state points of the cycle, (b) COP, (c) cycle refrigerating efficiency, and (d) rate of refrigerant flow.

Solution:

(a) Figure 9 shows a schematic p-h diagram for the problem with numerical property data. Saturated vapor and saturated liquid properties for states 1 and 3 are obtained from the saturation table for R-134a in Chapter 30. Properties for superheated vapor at state 2 are obtained by linear interpolation of the superheat tables for R-134a in Chapter 30. Specific volume and specific entropy values for state 4 are obtained by determining the quality of the liquid-vapor mixture from the enthalpy.

$$ x_4 = \frac{h_4 - h_f}{h_g - h_f} = \frac{241.72 - 173.64}{386.55 - 173.64} = 0.3198 $$

$$ v_4 = v_f + x_4(v_g - v_f) = 0.0007362 + 0.3198(0.14739 - 0.0007362) $$
$$ = 0.04764 \text{ m}^3/\text{kg} $$

$$ s_4 = s_f + x_4(s_g - s_f) = 0.9002 + 0.3198(1.7413 - 0.9002) $$
$$ = 1.16918 \text{ kJ/(kg·K)} $$

The property data are tabulated in Table 1.

(b) By Equation (40),

$$ \text{COP} = \frac{386.55 - 241.71}{423.07 - 386.55} = 3.97 $$

(c) By Equations (17) and (38),

$$ \eta_R = \frac{\text{COP}(T_3 - T_1)}{T_1} = \frac{(3.97)(50)}{253.15} = 0.78 \text{ or } 78\% $$

(d) The mass flow of refrigerant is obtained from an energy balance on the evaporator. Thus,

$$ m(h_1 - h_4) = Q_i = 50 \text{ kW} $$

and

$$ \text{COP} = \frac{{}_dQ_1}{W_{net}} = \frac{T_R}{T_0 - T_R} $$

The saturation temperatures of the single-stage cycle strongly influence the magnitude of the coefficient of performance. This influence may be readily appreciated by an area analysis on a temperature-entropy (T-s) diagram. The area under a reversible process line on a T-s diagram is directly proportional to the thermal energy added or removed from the working fluid. This observation follows directly from the definition of entropy [see Equation (8)]. $m = \frac{Q_i}{(h_1 - h_4)} = \frac{50}{(386.55 - 241.72)} = 0.345$ kg/s

Table 1 Thermodynamic Property Data for Example 2

State	t, °C	p, kPa	v, m³/kg	h, kJ/kg	s, kJ/(kg·K)

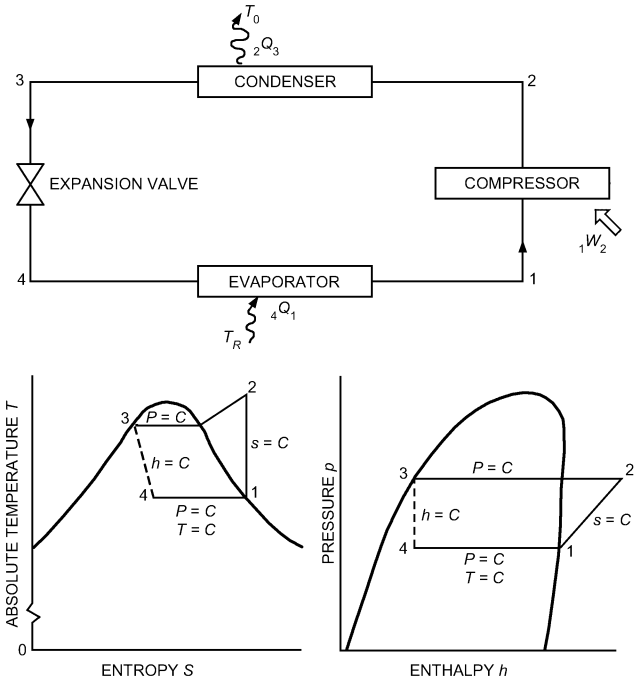

Fig. 8 Theoretical Single-Stage Vapor Compression Refrigeration Cycle

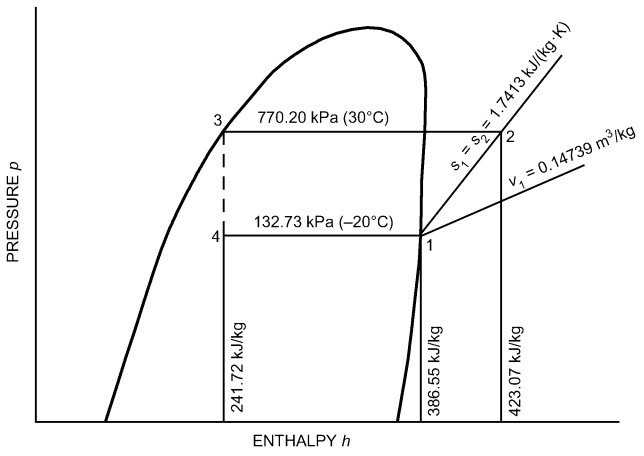

Fig. 9 Schematic p-h Diagram for Example 2

Licensed for single user. © 2021 ASHRAE, Inc.

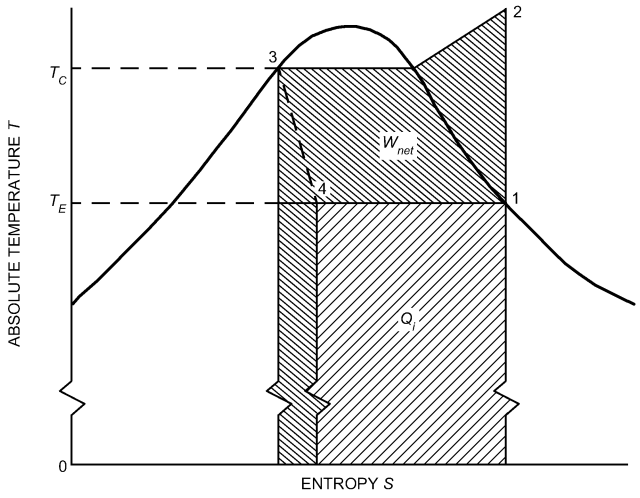

Fig. 10 Areas on *T-s* Diagram Representing Refrigerating Effect and Work Supplied for Theoretical Single-Stage Cycle

In Figure 10, the area representing Q_o is the total area under the constant-pressure curve between states 2 and 3. The area representing the refrigerating capacity Q_i is the area under the constant-pressure line connecting states 4 and 1. The net work required W_{net} equals the difference $(Q_o - Q_i)$, which is represented by the entire shaded area shown on Figure 10.

Because COP = Q_i/W_{net}, the effect on the COP of changes in evaporating temperature and condensing temperature may be observed. For example, a decrease in evaporating temperature T_E significantly increases W_{net} and slightly decreases Q_i. An increase in condensing temperature T_C produces the same results but with less effect on W_{net}. Therefore, for maximum coefficient of performance, the cycle should operate at the lowest possible condensing temperature and maximum possible evaporating temperature.

2.3 LORENZ REFRIGERATION CYCLE

The Carnot refrigeration cycle includes two assumptions that make it impractical. The heat transfer capacities of the two external fluids are assumed to be infinitely large so the external fluid temperatures remain fixed at T_0 and T_R (they become infinitely large thermal reservoirs). The Carnot cycle also has no thermal resistance between the working refrigerant and external fluids in the two heat exchange processes. As a result, the refrigerant must remain fixed at T_0 in the condenser and at T_R in the evaporator.

The Lorenz cycle eliminates the first restriction in the Carnot cycle by allowing the temperature of the two external fluids to vary during heat exchange. The second assumption of negligible thermal resistance between the working refrigerant and two external fluids remains. Therefore, the refrigerant temperature must change during the two heat exchange processes to equal the changing temperature of the external fluids. This cycle is completely reversible when operating between two fluids that each have a finite but constant heat capacity.

Figure 11 is a schematic of a Lorenz cycle. Note that this cycle does not operate between two fixed temperature limits. Heat is added to the refrigerant from state 4 to state 1. This process is assumed to be linear on *T-s* coordinates, which represents a fluid with constant heat capacity. The refrigerant temperature is increased in isentropic compression from state 1 to state 2. Process 2-3 is a heat rejection process in which the refrigerant temperature decreases linearly with heat transfer. The cycle ends with isentropic expansion between states 3 and 4.

The heat addition and heat rejection processes are parallel so the entire cycle is drawn as a parallelogram on *T-s* coordinates. A

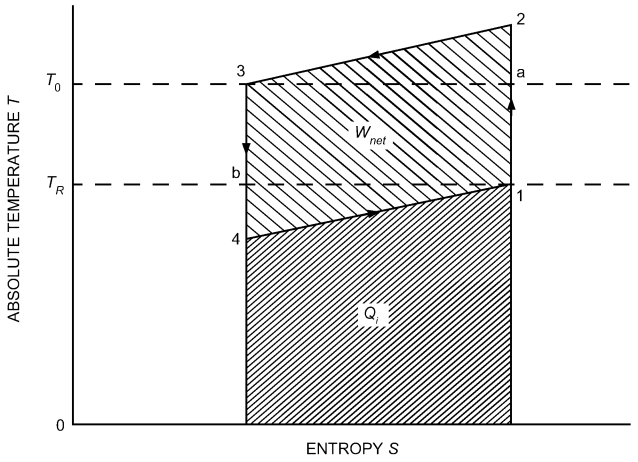

Fig. 11 Processes of Lorenz Refrigeration Cycle

Carnot refrigeration cycle operating between T_0 and T_R would lie between states 1, a, 3, and b; the Lorenz cycle has a smaller refrigerating effect and requires more work, but this cycle is a more practical reference when a refrigeration system operates between two single-phase fluids such as air or water.

The energy transfers in a Lorenz refrigeration cycle are as follows, where ΔT is the temperature change of the refrigerant during each of the two heat exchange processes.

$$Q_o = (T_0 + \Delta T/2)(S_2 - S_3)$$

$$Q_i = (T_R - \Delta T/2)(S_1 - S_4) = (T_R - \Delta T/2)(S_2 - S_3)$$

$$W_{net} = Q_o - Q_R$$

Thus by Equation (15),

$$\text{COP} = \frac{T_R - (\Delta T/2)}{T_0 - T_R + \Delta T} \tag{42}$$

Example 3. Determine the entropy change, work required, and COP for the Lorenz cycle shown in Figure 11 when the temperature of the refrigerated space is T_R = 250 K, ambient temperature is T_0 = 300 K, ΔT of the refrigerant is 5 K, and refrigeration load is 125 kJ.

Solution:

$$\Delta S = \int_4^1 \frac{\delta Q_i}{T} = \frac{Q_i}{T_R - (\Delta T/2)} = \frac{125}{247.5} = 0.5051 \text{ kJ/K}$$

$$Q_o = [T_0 + (\Delta T/2)]\Delta S = (300 + 2.5)0.5051 = 152.79 \text{ kJ}$$

$$W_{net} = Q_o - Q_R = 152.79 - 125 = 27.79 \text{ kJ}$$

$$\text{COP} = \frac{T_R - (\Delta T/2)}{T_0 - T_R + \Delta T} = \frac{250 - (5/2)}{300 - 250 + 5} = \frac{247.5}{55} = 4.50$$

$$\Delta S = \int_4^1 \frac{\delta Q_i}{T} = \frac{Q_i}{T_R - (\Delta T/2)} = \frac{125}{247.5} = 0.5051 \text{ kJ/K}$$

$$Q_o = [T_0 + (\Delta T/2)]\Delta S = (300 + 2.5)0.5051 = 152.79 \text{ kJ}$$

$$W_{net} = Q_o - Q_R = 152.79 - 125 = 27.79 \text{ kJ}$$

$$\text{COP} = \frac{T_R - (\Delta T/2)}{T_0 - T_R + \Delta T} = \frac{250 - (5/2)}{300 - 250 + 5} = \frac{247.5}{55} = 4.50$$

Note that the entropy change for the Lorenz cycle is larger than for the Carnot cycle when both operate between the same two temperature reservoirs and have the same capacity (see Example 1). That is, both the heat rejection and work requirement are larger for the Lorenz cycle. This difference is caused by the finite temperature

Licensed for single user. © 2021 ASHRAE, Inc.

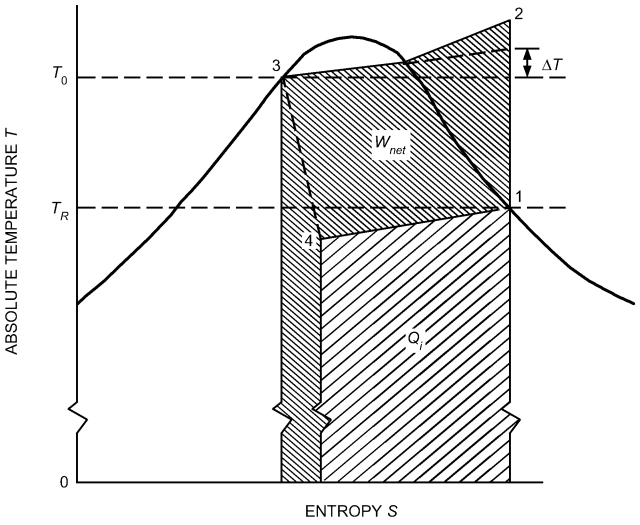

Fig. 12 Areas on *T-s* Diagram Representing Refrigerating Effect and Work Supplied for Theoretical Single-Stage Cycle Using Zeotropic Mixture as Refrigerant

difference between the working fluid in the cycle compared to the bounding temperature reservoirs. However, as discussed previously, the assumption of constant-temperature heat reservoirs is not necessarily a good representation of an actual refrigeration system because of the temperature changes that occur in the heat exchangers.

2.4 THEORETICAL SINGLE-STAGE CYCLE USING ZEOTROPIC REFRIGERANT MIXTURE

A practical method to approximate the Lorenz refrigeration cycle is to use a fluid mixture as the refrigerant and the four system components shown in Figure 8. When the mixture is not azeotropic and the phase change occurs at constant pressure, the temperatures change during evaporation and condensation and the theoretical single-stage cycle can be shown on *T-s* coordinates as in Figure 12. In comparison, Figure 10 shows the system operating with a pure simple substance or an azeotropic mixture as the refrigerant. Equations (14), (15), (39), (40), and (41) apply to this cycle and to conventional cycles with constant phase change temperatures. Equation (42) should be used as the reversible cycle COP in Equation (17).

For zeotropic mixtures, the concept of constant saturation temperatures does not exist. For example, in the evaporator, the refrigerant enters at T_4 and exits at a higher temperature T_1. The temperature of saturated liquid at a given pressure is the **bubble point** and the temperature of saturated vapor at a given pressure is called the **dew point**. The temperature T_3 in Figure 12 is at the bubble point at the condensing pressure and T_1 is at the dew point at the evaporating pressure.

Areas on a *T-s* diagram representing additional work and reduced refrigerating effect from a Lorenz cycle operating between the same two temperatures T_1 and T_3 with the same value for ΔT can be analyzed. The cycle matches the Lorenz cycle most closely when counterflow heat exchangers are used for both the condenser and evaporator.

In a cycle that has heat exchangers with finite thermal resistances and finite external fluid capacity rates, Kuehn and Gronseth (1986) showed that a cycle using a refrigerant mixture has a higher coefficient of performance than one using a simple pure substance as a refrigerant. However, the improvement in COP is usually small. Mixture performance can be improved further by reducing the heat exchangers' thermal resistance and passing fluids through them in a counterflow arrangement.

2.5 MULTISTAGE VAPOR COMPRESSION REFRIGERATION CYCLES

Multistage or multipressure vapor compression refrigeration is used when several evaporators are needed at various temperatures, such as in a supermarket, or when evaporator temperature becomes very low. Low evaporator temperature indicates low evaporator pressure and low refrigerant density into the compressor. Two small compressors in series have a smaller displacement and usually operate more efficiently than one large compressor that covers the entire pressure range from the evaporator to the condenser. This is especially true in ammonia refrigeration systems because of the large amount of superheating that occurs during the compression process.

Thermodynamic analysis of multistage cycles is similar to analysis of single-stage cycles, except that mass flow differs through various components of the system. A careful mass balance and energy balance on individual components or groups of components ensures correct application of the first law of thermodynamics. Care must also be used when performing second-law calculations. Often, the refrigerating load is comprised of more than one evaporator, so the total system capacity is the sum of the loads from all evaporators. Likewise, the total energy input is the sum of the work into all compressors. For multistage cycles, the expression for the coefficient of performance given in Equation (15) should be written as

$$\text{COP} = \sum Q_i / W_{net} \tag{43}$$

When compressors are connected in series, vapor between stages should be cooled to bring the vapor to saturated conditions before proceeding to the next stage of compression. Intercooling usually minimizes displacement of the compressors, reduces the work requirement, and increases the cycle's COP. If the refrigerant temperature between stages is above ambient, a simple intercooler that removes heat from the refrigerant can be used. If the temperature is below ambient, which is the usual case, the refrigerant itself must be used to cool the vapor. This is accomplished with a flash intercooler. Figure 13 shows a cycle with a flash intercooler installed.

The superheated vapor from compressor I is bubbled through saturated liquid refrigerant at the intermediate pressure of the cycle. Some of this liquid is evaporated when heat is added from the superheated refrigerant. The result is that only saturated vapor at the intermediate pressure is fed to compressor II. A common approach is to operate the intercooler at about the geometric mean of the evaporating and condensing pressures. This operating point provides the same pressure ratio and nearly equal volumetric efficiencies for the two compressors. Example 4 illustrates the thermodynamic analysis of this cycle.

Example 4. Determine the thermodynamic properties of the eight state points shown in Figure 13, mass flows, and COP of this theoretical multistage refrigeration cycle using R-134a. The saturated evaporator temperature is –20°C, the saturated condensing temperature is 30°C, and the refrigeration load is 50 kW. The saturation temperature of the refrigerant in the intercooler is 0°C, which is nearly at the geometric mean pressure of the cycle.

Solution:

Thermodynamic property data are obtained from the saturation and superheat tables for R-134a in Chapter 30. States 1, 3, 5, and 7 are obtained directly from the saturation table. State 6 is a mixture of liquid and vapor. The quality is calculated by

$$x_6 = \frac{h_6 - h_7}{h_3 - h_7} = \frac{241.72 - 200}{398.60 - 200} = 0.21007$$

Then,

$$v_6 = v_7 + x_6(v_3 - v_7) = 0.000772 + 0.21007(0.06931 - 0.000772)$$
$$= 0.01517 \text{ m}^3/\text{kg}$$

Licensed for single user. © 2021 ASHRAE, Inc.

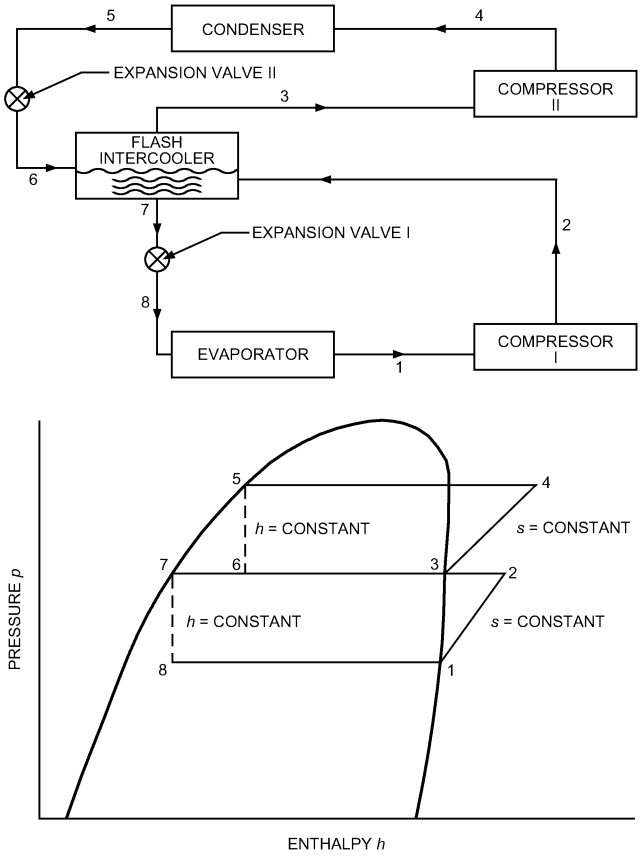

Fig. 13 Schematic and Pressure-Enthalpy Diagram for Dual-Compression, Dual-Expansion Cycle of Example 4

$$s_6 = s_7 + x_6(s_3 - s_7) = 1.0 + 0.21007(1.7282 - 1.0)$$
$$= 1.15297 \text{ kJ/(kg·K)}$$

Similarly for state 8,

$$x_8 = 0.12381, \quad v_8 = 0.01889 \text{ m}^3/\text{kg}, \quad s_8 = 1.00434 \text{ kJ/(kg·K)}$$

States 2 and 4 are obtained from the superheat tables by linear interpolation. The thermodynamic property data are summarized in Table 2.

Mass flow through the lower circuit of the cycle is determined from an energy balance on the evaporator.

$$\dot{m}_1 = \frac{\dot{Q}_i}{h_1 - h_8} = \frac{50}{386.55 - 200} = 0.2680 \text{ kg/s}$$

$$\dot{m}_1 = \dot{m}_2 = \dot{m}_7 = \dot{m}_8$$

For the upper circuit of the cycle,

$$\dot{m}_3 = \dot{m}_4 = \dot{m}_5 = \dot{m}_6$$

Assuming the intercooler has perfect external insulation, an energy balance on it is used to compute $\dot{m}_3$.

$$\dot{m}_6 h_6 + \dot{m}_2 h_2 = \dot{m}_7 h_7 + \dot{m}_3 h_3$$

Rearranging and solving for $\dot{m}_3$,

$$\dot{m}_3 = \dot{m}_2 \frac{h_7 - h_2}{h_6 - h_3} = 0.2680 \frac{200 - 401.51}{241.72 - 398.60} = 0.3442 \text{ kg/s}$$

$$W_{\text{I}} = \dot{m}_1(h_2 - h_1) = 0.2680(401.51 - 386.55)$$
$$= 4.009 \text{ kW}$$

$$W_{\text{II}} = \dot{m}_3(h_4 - h_3) = 0.3442(418.68 - 398.60)$$
$$= 6.912 \text{ kW}$$

$$\text{COP} = \frac{\dot{Q}_i}{W_{\text{I}} + W_{\text{II}}} = \frac{50}{4.009 + 6.912} = 4.58$$

Table 2 Thermodynamic Property Values for Example 4

State	Temperature, °C	Pressure, kPa	Specific Volume, m³/kg	Specific Enthalpy, kJ/kg	Specific Entropy, kJ/(kg·K)
1	–20.0	132.73	0.14739	386.55	1.7413
2	2.8	292.80	0.07097	401.51	1.7413
3	0.0	292.80	0.06931	398.60	1.7282
4	33.6	770.20	0.02726	418.68	1.7282
5	30.0	770.20	0.00084	241.72	1.1435
6	0.0	292.80	0.01517	241.72	1.15297
7	0.0	292.80	0.000772	200.00	1.0000
8	–20.0	132.73	0.01889	200.00	1.00434

Examples 2 and 4 have the same refrigeration load and operate with the same evaporating and condensing temperatures. The two-stage cycle in Example 4 has a higher COP and less work input than the single-stage cycle. Also, the highest refrigerant temperature leaving the compressor is about 34°C for the two-stage cycle versus about 38°C for the single-stage cycle. These differences are more pronounced for cycles operating at larger pressure ratios.

2.6 ACTUAL REFRIGERATION SYSTEMS

Actual systems operating steadily differ from the ideal cycles considered in the previous sections in many respects. Pressure drops occur everywhere in the system except in the compression process. Heat transfers between the refrigerant and its environment in all components. The actual compression process differs substantially from isentropic compression. The working fluid is not a pure substance but a mixture of refrigerant and oil. All of these deviations from a theoretical cycle cause irreversibilities in the system. Each irreversibility requires additional power into the compressor. It is useful to understand how these irreversibilities are distributed throughout a real system; this insight can be useful when design changes are contemplated or operating conditions are modified. Example 5 illustrates how the irreversibilities can be computed in a real system and how they require additional compressor power to overcome. Input data have been rounded off for ease of computation.

Example 5. An air-cooled, direct-expansion, single-stage mechanical vapor-compression refrigerator uses R-22 and operates under steady conditions. A schematic of this system is shown in Figure 14. Pressure drops occur in all piping, and heat gains or losses occur as indicated. Power input includes compressor power and the power required to operate both fans. The following performance data are obtained:

Ambient air temperature	t_0	=	30°C
Refrigerated space temperature	t_R	=	–10°C
Refrigeration load	$\dot{Q}_{evap}$	=	7.0 kW
Compressor power input	W_{comp}	=	2.5 kW
Condenser fan input	W_{CF}	=	0.15 kW
Evaporator fan input	W_{EF}	=	0.11 kW

Refrigerant pressures and temperatures are measured at the seven locations shown in Figure 14. Table 3 lists the measured and computed thermodynamic properties of the refrigerant, neglecting the dissolved oil. A pressure-enthalpy diagram of this cycle is shown in Figure 15 and is compared with a theoretical single-stage cycle operating between the air temperatures t_R and t_0.

Compute the energy transfers to the refrigerant in each component of the system and determine the second-law irreversibility rate in each component. Show that the total irreversibility rate multiplied by the absolute ambient temperature is equal to the difference between the actual power input and the power required by a Carnot cycle operating between t_R and t_0 with the same refrigerating load.

Solution: The mass flow of refrigerant is the same through all components, so it is only computed once through the evaporator. Each component in the system is analyzed sequentially, beginning with the evaporator. Equation (6) is used to perform a first-law energy balance on each component, and Equations (11) and (13) are used for the

Second law

$$ {}_3\dot{I}_4 = \dot{m}(s_4 - s_3) - \frac{{}_3\dot{Q}_4}{T_0} $$

$$ = 0.04322(1.7891 - 1.8165) - (-0.4274/303.15) $$

$$ = 0.2258 \text{ W/K} $$

Condenser:

Energy balance

$$ {}_4\dot{Q}_5 = \dot{m}(h_5 - h_4) $$

$$ = 0.04322(241.4 - 444.31) = -8.7698 \text{ kW} $$

Second law

$$ {}_4\dot{I}_5 = \dot{m}(s_5 - s_4) - \frac{{}_4\dot{Q}_5}{T_0} $$

$$ = 0.04322(1.1400 - 1.7891) - (-8.7698/303.15) $$

$$ = 0.8747 \text{ W/K} $$

Liquid Line:

Energy balance

$$ {}_5\dot{Q}_6 = \dot{m}(h_6 - h_5) $$

$$ = 0.04322(240.13 - 241.40) = -0.0549 \text{ kW} $$

Licensed for single user. © 2021 ASHRAE, Inc.

Second law

$$ {}_5\dot{I}_6 = \dot{m}(s_6 - s_5) - \frac{{}_5\dot{Q}_6}{T_0} $$

$$ = 0.04322(1.1359 - 1.1400) - (-0.0549/303.15) = 0.0039 \text{ W/K} $$

Expansion Device:

Energy balance

$$ {}_6\dot{Q}_7 = \dot{m}(h_7 - h_6) = 0 $$

Second law

$$ {}_6\dot{I}_7 = \dot{m}(s_7 - s_6) = 0.04322(1.1561 - 1.1359) = 0.8730 \text{ W/K} $$

These results are summarized in Table 4. For the Carnot cycle,

$$ \text{COP}_{Carnot} = \frac{T_R}{T_0 - T_R} = \frac{263.15}{40} = 6.579 $$

The Carnot power requirement for the 7 kW load is

$$ \dot{W}_{Carnot} = \frac{\dot{Q}_e}{\text{COP}_{Carnot}} = \frac{7.0}{6.579} = 1.064 \text{ kW} $$

The actual power requirement for the compressor is

$$ \dot{W}_{comp} = \dot{W}_{Carnot} + \dot{I}_{total} T_0 $$

$$ = 1.064 + \frac{4.7351(303.15)}{1000} = 2.4994 \text{ kW} $$

This result is within computational error of the measured power input to the compressor of 2.5 kW.

The analysis in Example 5 can be applied to any actual vapor compression refrigeration system. The only required information for second-law analysis is the refrigerant thermodynamic state points and mass flow rates and the temperatures in which the system is exchanging heat. In this example, the extra compressor power required to overcome the irreversibility in each component is determined. The component with the largest loss is the compressor. This loss is due to motor inefficiency, friction losses, and irreversibilities caused by pressure drops, mixing, and heat transfer between the compressor and the surroundings. Unrestrained expansion in the expansion device is the next largest (also a large loss), but could be reduced by using an expander rather than a throttling process. An expander may be economical on large machines.

All heat transfer irreversibilities on both the refrigerant side and the air side of the condenser and evaporator are included in the analysis. Refrigerant pressure drop is also included. Air-side pressure drop irreversibilities of the two heat exchangers are not included, but these are equal to the fan power requirements because all the fan power is dissipated as heat.

An overall second-law analysis, such as in Example 5, shows the designer components with the most losses, and helps determine which components should be replaced or redesigned to improve performance. However, it does not identifythe nature of the losses; this requires a more detailed second-law analysis of the actual processes in terms of fluid flow and heat transfer (Liang and Kuehn 1991). A detailed analysis shows that most irreversibilities associated with heat exchangers are due to heat transfer, whereas air-side pressure drop causes a very small loss and refrigerant pressure drop causes a negligible loss. This finding indicates that promoting refrigerant heat transfer at the expense of increasing the pressure drop often improves performance. Using a thermoeconomic technique is required to determine the cost/benefits associated with reducing component irreversibilities.

3. ABSORPTION REFRIGERATION CYCLES

An absorption cycle is a heat-activated thermal cycle. It exchanges only thermal energy with its surroundings; no appreciable mechanical energy is exchanged. Furthermore, no appreciable conversion of heat to work or work to heat occurs in the cycle.

Absorption cycles are used in applications where one or more of the exchanges of heat with the surroundings is the useful product (e.g., refrigeration, air conditioning, and heat pumping). The two great advantages of this type of cycle in comparison to other cycles with similar product are

- No large, rotating mechanical equipment is required
- Any source of heat can be used, including low-temperature sources (e.g., waste heat, solar heat)

3.1 IDEAL THERMAL CYCLE

All absorption cycles include at least three thermal energy exchanges with their surroundings (i.e., energy exchange at three different temperatures). The highest- and lowest-temperature heat flows are in one direction, and the mid-temperature one (or two) is in the opposite direction. In the **forward cycle**, the extreme (hottest and coldest) heat flows are into the cycle. This cycle is also called the heat amplifier, heat pump, conventional cycle, or Type I cycle. When extreme-temperature heat flows are out of the cycle, it is called a **reverse cycle**, heat transformer, temperature amplifier, temperature booster, or Type II cycle. Figure 16 illustrates both types of thermal cycles.

This fundamental constraint of heat flow into or out of the cycle at three or more different temperatures establishes the first limitation on cycle performance. By the first law of thermodynamics (at steady state),

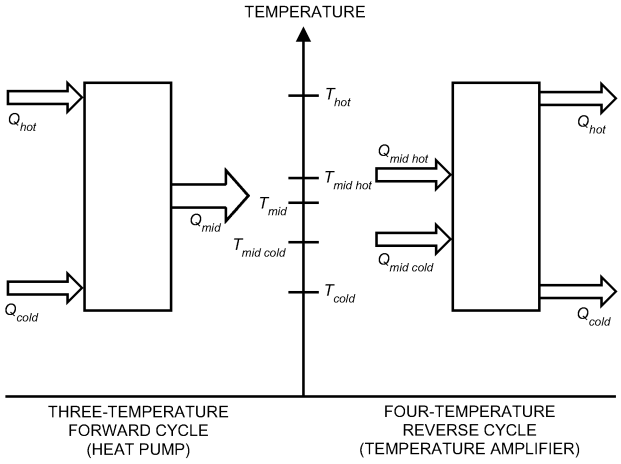

Fig. 16 Thermal Cycles

Licensed for single user. © 2021 ASHRAE, Inc.

$$Q_{hot} + Q_{cold} = -Q_{mid} \quad (44)$$

(positive heat quantities are into the cycle)

The second law requires that

$$\frac{Q_{hot}}{T_{hot}} + \frac{Q_{cold}}{T_{cold}} + \frac{Q_{mid}}{T_{mid}} \geq 0 \quad (45)$$

with equality holding in the ideal case.

From these two laws alone (i.e., without invoking any further assumptions) it follows that, for the ideal forward cycle,

$$\text{COP}_{ideal} = \frac{Q_{cold}}{Q_{hot}} = \frac{T_{hot} - T_{mid}}{T_{hot}} \times \frac{T_{cold}}{T_{mid} - T_{cold}} \quad (46)$$

The heat ratio Q_{cold}/Q_{hot} is commonly called the **coefficient of performance (COP)**, which is the cooling realized divided by the driving heat supplied.

Heat rejected to ambient may be at two different temperatures, creating a **four-temperature cycle**. The ideal COP of the four-temperature cycle is also expressed by Equation (46), with T_{mid} signifying the entropic mean heat rejection temperature. In that case, T_{mid} is calculated as follows:

$$T_{mid} = \frac{Q_{mid\ hot} + Q_{mid\ cold}}{\frac{Q_{mid\ hot}}{T_{mid\ hot}} + \frac{Q_{mid\ cold}}{T_{mid\ cold}}} \quad (47)$$

This expression results from assigning all the entropy flow to the single temperature T_{mid}.

The ideal COP for the four-temperature cycle requires additional assumptions, such as the relationship between the various heat quantities. Under the assumptions that $Q_{cold} = Q_{mid\ cold}$ and $Q_{hot} = Q_{mid\ hot}$, the following expression results:

$$\text{COP}_{ideal} = \frac{T_{hot} - T_{mid\ hot}}{T_{hot}} \times \frac{T_{cold}}{T_{mid\ cold}} \times \frac{T_{cold}}{T_{mid\ hot}} \quad (48)$$

3.2 WORKING-FLUID PHASE CHANGE CONSTRAINTS

Absorption cycles require at least two working substances: a sorbent and a fluid refrigerant; these substances undergo phase changes. Given this constraint, many combinations are not achievable. The first result of invoking the phase change constraints is that the various heat flows assume known identities. As shown in Figure 17, the refrigerant phase changes occur in an evaporator and a condenser, and the sorbent phase changes in an absorber and a desorber (generator). (Note that two lines connect the evaporator to the absorber and the desorber to the condenser, with one indicating vapor flow, the second carryover of liquid. In both cases, the carryover of liquid is detrimental to system performance.) For the **forward absorption cycle**, the highest-temperature heat is always supplied to the generator,

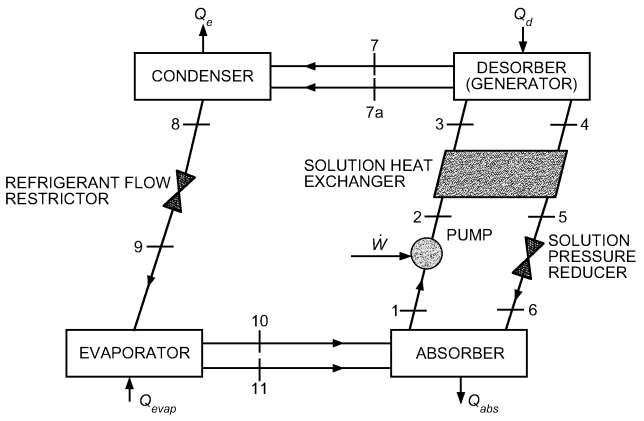

Fig. 17 Single-Effect Absorption Cycle

$$Q_{hot} \equiv Q_{gen} \quad (49)$$

and the coldest heat is supplied to the evaporator:

$$Q_{cold} \equiv Q_{evap} \quad (50)$$

For the **reverse absorption cycle** (also called **heat transformer** or **type II absorption cycle**), the highest-temperature heat is rejected from the absorber, and the lowest-temperature heat is rejected from the condenser.

The second result of the phase change constraint is that, for all known refrigerants and sorbents over pressure ranges of interest,

$$Q_{evap} \approx Q_{cond} \quad (51)$$

and

$$Q_{gen} \approx Q_{abs} \quad (52)$$

These two relations are true because the latent heat of phase change (vapor ↔ condensed phase) is relatively constant when far removed from the critical point. Thus, each heat input cannot be independently adjusted.

The ideal single-effect forward-cycle COP expression is

$$\text{COP}_{ideal} \leq \frac{T_{gen} - T_{abs}}{T_{gen}} \times \frac{T_{evap}}{T_{cond} - T_{evap}} \times \frac{T_{cond}}{T_{abs}} \quad (53)$$

Equality holds only if the heat quantities at each temperature may be adjusted to specific values, which is not possible, as shown the following discussion.

The third result of invoking the phase change constraint is that only three of the four temperatures T_{evap}, T_{cond}, T_{gen}, and T_{abs} may be independently selected.

Practical liquid absorbents for absorption cycles have a significant negative deviation from behavior predicted by Raoult's law. This has the beneficial effect of reducing the required amount of absorbent recirculation, at the expense of reduced **lift** ($T_{cond} - T_{evap}$) and increased sorption duty. In practical terms, for most absorbents,

$$Q_{abs}/Q_{cond} \approx 1.2 \text{ to } 1.3 \quad (54)$$

and

$$T_{gen} - T_{abs} \approx 1.2(T_{cond} - T_{evap}) \quad (55)$$

The net result of applying these approximations and constraints to the ideal-cycle COP for the single-effect forward cycle is

$$\text{COP}_{ideal} \approx 1.2\frac{T_{evap}T_{cond}}{T_{gen}T_{abs}} \approx \frac{Q_{cond}}{Q_{abs}} \approx 0.8 \quad (56)$$

In practical terms, the temperature constraint reduces the ideal COP to about 0.9, and the heat quantity constraint further reduces it to about 0.8.

Another useful result is

$$T_{gen\ min} = T_{cond} + T_{abs} - T_{evap} \quad (57)$$

where $T_{gen\ min}$ is the minimum generator temperature necessary to achieve a given evaporator temperature.

Alternative approaches are available that lead to nearly the same upper limit on ideal-cycle COP. For example, one approach equates the exergy production from a "driving" portion of the cycle to the

Licensed for single user. © 2021 ASHRAE, Inc.

exergy consumption in a "cooling" portion of the cycle (Tozer and James 1997). This leads to the expression

$$\text{COP}_{ideal} \leq \frac{T_{evap}}{T_{abs}} = \frac{T_{cond}}{T_{gen}} \quad (58)$$

Another approach derives the idealized relationship between the two temperature differences that define the cycle: the cycle lift, defined previously, and **drop** ($T_{gen} - T_{abs}$).

Temperature Glide

One important limitation of simplified analysis of absorption cycle performance is that the heat quantities are assumed to be at fixed temperatures. In most actual applications, there is some temperature change (**temperature glide**) in the various fluids supplying or acquiring heat. It is most easily described by first considering situations wherein temperature glide is not present (i.e., truly isothermal heat exchanges). Examples are condensation or boiling of pure components (e.g., supplying heat by condensing steam). Any sensible heat exchange relies on temperature glide: for example, a circulating high-temperature liquid as a heat source; cooling water or air as a heat rejection medium; or circulating chilled glycol. Even latent heat exchanges can have temperature glide, as when a multicomponent mixture undergoes phase change.

When the temperature glide of one fluid stream is small compared to the cycle lift or drop, that stream can be represented by an average temperature, and the preceding analysis remains representative. However, one advantage of absorption cycles is they can maximize benefit from low-temperature, high-glide heat sources. That ability derives from the fact that the desorption process inherently embodies temperature glide, and hence can be tailored to match the heat source glide. Similarly, absorption also embodies glide, which can be made to match the glide of the heat rejection medium.

Implications of temperature glide have been analyzed for power cycles (Ibrahim and Klein 1998), but not yet for absorption cycles.

3.3 WORKING FLUIDS

Working fluids for absorption cycles fall into four categories, each requiring a different approach to cycle modeling and thermodynamic analysis. Liquid absorbents can be **nonvolatile** (i.e., vapor phase is always pure refrigerant, neglecting condensables) or **volatile** (i.e., vapor concentration varies, so cycle and component modeling must track both vapor and liquid concentration). Solid sorbents can be grouped by whether they are **physisorbents** (also known as *adsorbents*), for which, as for liquid absorbents, sorbent temperature depends on both pressure and refrigerant loading (bivariance); or **chemisorbents** (also known as **complex compounds**), for which sorbent temperature does not vary with loading, at least over small ranges.

Beyond these distinctions, various other characteristics are either necessary or desirable for suitable liquid absorbent/refrigerant pairs, as follows:

Absence of Solid Phase (Solubility Field). The refrigerant/absorbent pair should not solidify over the expected range of composition and temperature. If a solid forms, it will stop flow and shut down equipment. Controls must prevent operation beyond the acceptable solubility range.

Relative Volatility. The refrigerant should be much more volatile than the absorbent so the two can be separated easily. Otherwise, cost and heat requirements may be excessive. Many absorbents are effectively nonvolatile.

Affinity. The absorbent should have a strong affinity for the refrigerant under conditions in which absorption takes place. Affinity means a negative deviation from Raoult's law and results in an activity coefficient of less than unity for the refrigerant. Strong affinity allows less absorbent to be circulated for the same refrigeration effect, reducing sensible heat losses, and allows a smaller liquid heat exchanger to transfer heat from the absorbent to the pressurized refrigerant/absorption solution. On the other hand, as affinity increases, extra heat is required in the generators to separate refrigerant from the absorbent, and the COP suffers.

Pressure. Operating pressures, established by the refrigerant's thermodynamic properties, should be moderate. High pressure requires heavy-walled equipment, and significant electrical power may be needed to pump fluids from the low-pressure side to the high-pressure side. Vacuum requires large-volume equipment and special means of reducing pressure drop in the refrigerant vapor paths.

Stability. High chemical stability is required because fluids are subjected to severe conditions over many years of service. Instability can cause undesirable formation of gases, solids, or corrosive substances. Purity of all components charged into the system is critical for high performance and corrosion prevention.

Corrosion. Most absorption fluids corrode materials used in construction. Therefore, corrosion inhibitors are used.

Safety. Precautions as dictated by code are followed when fluids are toxic, inflammable, or at high pressure. Codes vary according to country and region.

Transport Properties. Viscosity, surface tension, thermal diffusivity, and mass diffusivity are important characteristics of the refrigerant/absorbent pair. For example, low viscosity promotes heat and mass transfer and reduces pumping power.

Latent Heat. The refrigerant latent heat should be high, so the circulation rate of the refrigerant and absorbent can be minimized.

Environmental Soundness. The two parameters of greatest concern are the global warming potential (GWP) and the ozone depletion potential (ODP). For more information on GWP and ODP, see Chapter 29.

No refrigerant/absorbent pair meets all requirements, and many requirements work at cross-purposes. For example, a greater solubility field goes hand in hand with reduced relative volatility. Thus, selecting a working pair is inherently a compromise.

Water/lithium bromide and ammonia/water offer the best compromises of thermodynamic performance and have no known detrimental environmental effect (zero ODP and zero GWP).

Ammonia/water meets most requirements, but its volatility ratio is low and it requires high operating pressures. Ammonia is also a Safety Code Group B2 fluid (ASHRAE *Standard* 34), which restricts its use indoors.

Advantages of water/lithium bromide include high (1) safety, (2) volatility ratio, (3) affinity, (4) stability, and (5) latent heat. However, this pair tends to form solids and operates at deep vacuum. Because the refrigerant turns to ice at 0°C, it cannot be used for low-temperature refrigeration. In fact, ice formation on demisters can be observed at even slightly above 0°C. Lithium bromide (LiBr) crystallizes at moderate concentrations, as would be encountered in air-cooled chillers, which ordinarily limits the pair to applications where the absorber is water cooled and the concentrations are lower. However, using a combination of salts as the absorbent can reduce this crystallization tendency enough to allow air cooling (Macriss 1968). Other disadvantages include low operating pressures and high viscosity. This is particularly detrimental to the absorption step; however, alcohols with a high relative molecular mass enhance LiBr absorption. Proper equipment design and additives can overcome these disadvantages.

Other refrigerant/absorbent pairs are listed in Table 5 (Macriss and Zawacki 1989). Several appear suitable for certain cycles and may solve some problems associated with traditional pairs. However, information on properties, stability, and corrosion is limited. Also, some of the fluids are somewhat hazardous.

Table 5 Refrigerant/Absorbent Pairs

Refrigerant	Absorbents
H_2O	Salts
	Alkali halides
	LiBr
	$LiClO_3$
	$CaCl_2$
	$ZnCl_2$
	ZnBr
	Alkali nitrates
	Alkali thiocyanates
	Bases
	Alkali hydroxides
	Acids
	H_2SO_4
	H_3PO_4
NH_3	H_2O
	Alkali thiocyanates
TFE	NMP
(Organic)	E181
	DMF
	Pyrrolidone
SO_2	Organic solvents

Alcohols such as methanol are also being considered as refrigerants. A review of working pairs is given in Macriss et al. (1988). In addition, some absorption working pairs use a conventional refrigerant, such as ammonia or water, but a solid absorbent. Examples are complex compounds in which ammonia is absorbed into solid salts that remain solid even when the salts absorb quantities of ammonia that exceed on a molar basis several times the moles of salt (Rockenfeller and Kirol 1989, 1996; Rockenfeller et al. 1992, 1993).

3.4 EFFECT OF FLUID PROPERTIES ON CYCLE PERFORMANCE

Thermodynamic observations can predict general trends of how working fluids' properties affect a cycle's performance: in all four major heat exchangers (absorber, generator, condenser, and evaporator), the amount of heat exchanged is dominated by the latent heat of the refrigerant (i.e., the component that undergoes the phase change), when any phase change of the absorbent is neglected. There are two additional contributions for the absorber and generator: heat of mixing when the condensed refrigerant is mixed with the absorbent/refrigerant solution, and heating or cooling of the refrigerant/absorbent mixture during the absorption or desorption process.

Thus, the heat requirement of the generator can be estimated as the latent heat of the refrigerant plus the heat of mixing plus the heat required to heat the remaining absorbent/refrigerant solution. Both additional terms increase the generator heat requirement and thus reduce the overall cycle efficiency. Based on this observation, the ideal absorption working fluid should have high latent heat, no heat of mixing, and a low specific heat capacity.

Furthermore, heat exchanged in the solution heat exchanger is governed by the specific heat of the fluid mixture flowing through this device. Consequently, any ineffectiveness of the heat exchanger represents a loss in absorption-cycle performance that is directly related to the specific heat capacity of the fluid mixture, reinforcing the argument that a low specific heat capacity is desirable.

Finally, losses in the expansion process of the refrigerant as it enters the evaporator are also governed by the latent heat of the refrigerant (preferably large) and its specific heat capacity (preferably small), so that as little refrigerant as possible evaporates as a result of the expansion process.

Absorption working fluids should consist of refrigerants with large latent heat and absorbents with a small heat of mixing, and both absorbent and refrigerant should have as small a specific heat capacity as possible.

Heat of mixing and latent heat are determined by functional groups within the molecule; specific heat capacity is minimized when the molecule is small and of low molecular mass. Therefore, ideal working fluids should be small molecules with as many functional groups as possible. This explains why ammonia and water are still the favored refrigerants to date for absorption cycles, and why organic fluids have not yet succeeded in commercial absorption cycle applications (because of their relatively large molecular mass).

3.5 ABSORPTION CYCLE REPRESENTATIONS

The quantities of interest to absorption cycle designers are temperature, concentration, pressure, and enthalpy. The most useful plots use linear scales and plot the key properties as straight lines. Some of the following plots are used:

- **Absorption plots** embody the vapor-liquid equilibrium of both the refrigerant and the sorbent. Plots on linear pressure-temperature coordinates have a logarithmic shape and hence are little used.
- In the **van't Hoff plot** ($\ln P$ versus $-1/T$), the constant concentration contours plot as nearly straight lines. Thus, it is more readily constructed (e.g., from sparse data) in spite of the awkward coordinates.
- The **Dühring diagram** (solution temperature versus reference temperature) retains the linearity of the van't Hoff plot but eliminates the complexity of nonlinear coordinates. Thus, it is used extensively (see Figure 20). The primary drawback is the need for a reference substance.
- The **Gibbs plot** (solution temperature versus $T \ln P$) retains most of the advantages of the Dühring plot (linear temperature coordinates, concentration contours are straight lines) but eliminates the need for a reference substance.
- The **Merkel plot** (enthalpy versus concentration) is used to assist thermodynamic calculations and to solve the distillation problems that arise with volatile absorbents. It has also been used for basic cycle analysis.
- **Temperature/entropy coordinates** are occasionally used to relate absorption cycles to their mechanical vapor compression counterparts.

3.6 CONCEPTUALIZING THE CYCLE

The basic absorption cycle shown in Figure 17 must be altered in many cases to take advantage of the available energy. Examples include the following: (1) the driving heat is much hotter than the minimum required $T_{gen\ min}$: a multistage cycle boosts the COP; and (2) the driving heat temperature is below $T_{gen\ min}$: a different multistage cycle (half-effect cycle) can reduce the $T_{gen\ min}$.

Multistage cycles have one or more of the four basic exchangers (generator, absorber, condenser, evaporator) present at two or more places in the cycle at different pressures or concentrations. A **multieffect** cycle is a special case of multistaging, signifying the number of times the driving heat is used in the cycle. Thus, there are several types of two-stage cycles: double-effect, half-effect, and triple-effect.

Two or more single-effect absorption cycles, such as shown in Figure 17, can be combined to form a multistage cycle by coupling any of the components. **Coupling** implies either (1) sharing component(s) between the cycles to form an integrated single hermetic cycle or (2) exchanging heat between components belonging to two hermetically separate cycles that operate at (nearly) the same temperature level.

Licensed for single user. © 2021 ASHRAE, Inc.

Figure 18 shows a **double-effect absorption cycle** formed by coupling the absorbers and evaporators of two single-effect cycles into an integrated, single hermetic cycle. Heat is transferred between the high-pressure condenser and intermediate-pressure generator. The heat of condensation of the refrigerant (generated in the high-temperature generator) generates additional refrigerant in the lower-temperature generator. Thus, the prime energy provided to the high-temperature generator is **cascaded** (used) twice in the cycle, making it a double-effect cycle. With the generation of additional refrigerant from a given heat input, the cycle COP increases. Commercial water/lithium bromide chillers normally use this cycle. The cycle COP can be further increased by coupling additional components and by increasing the number of cycles that are combined. This way, several different multieffect cycles can be combined by pressure-staging and/or concentration-staging. The double-effect cycle, for example, is formed by pressure staging two single-effect cycles.

Figure 19 shows twelve generic triple-effect cycles identified by Alefeld and Radermacher (1994). Cycle 5 is a pressure-staged cycle, and cycle 10 is a concentration-staged cycle. All other cycles are pressure and concentration staged. Cycle 1, which is a type of dual-loop cycle, is the only cycle consisting of two loops that does not circulate absorbent in the low-temperature portion of the cycle.

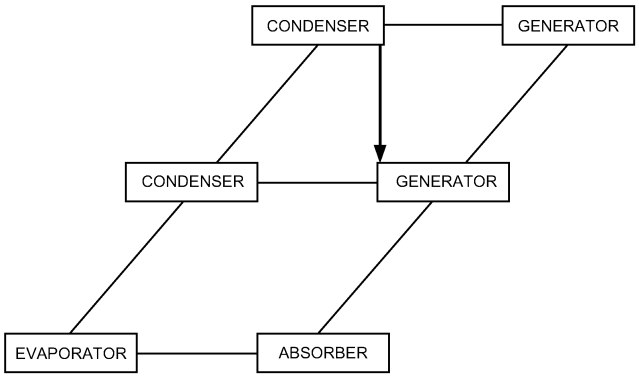

Fig. 18 Double-Effect Absorption Cycle

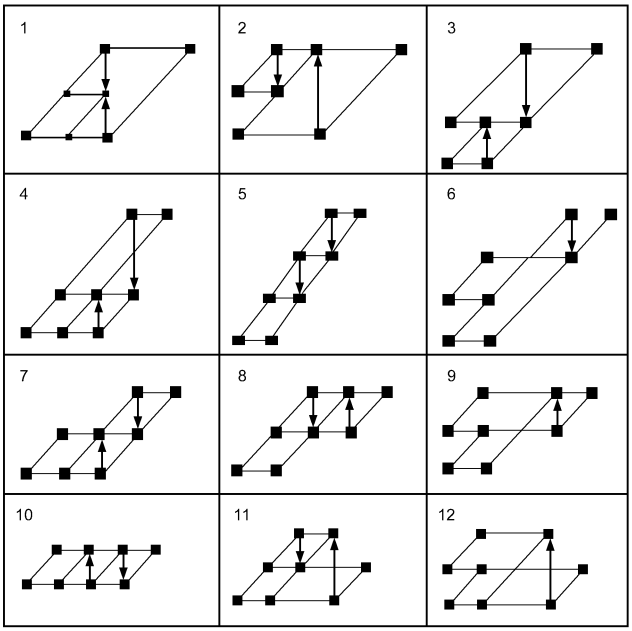

Fig. 19 Generic Triple-Effect Cycles

Each of the cycles shown in Figure 19 can be made with one, two, or sometimes three separate **hermetic loops**. Dividing a cycle into separate hermetic loops allows the use of a different working fluid in each loop. Thus, a corrosive and/or high-lift absorbent can be restricted to the loop where it is required, and a conventional additive-enhanced absorbent can be used in other loops to reduce system cost significantly. As many as 78 hermetic loop configurations can be synthesized from the twelve triple-effect cycles shown in Figure 19. For each hermetic loop configuration, further variations are possible according to the absorbent flow pattern (e.g., series or parallel), the absorption working pairs selected, and various other hardware details. Thus, literally thousands of distinct variations of the triple-effect cycle are possible.

The ideal analysis can be extended to these multistage cycles (Alefeld and Radermacher 1994). A similar range of cycle variants is possible for situations calling for the half-effect cycle, in which the available heat source temperature is below $t_{gen\ min}$.

3.7 ABSORPTION CYCLE MODELING

Analysis and Performance Simulation

A physical-mathematical model of an absorption cycle consists of four types of thermodynamic equations: mass balances, energy balances, relations describing heat and mass transfer, and equations for thermophysical properties of the working fluids.

As an example of simulation, Figure 20 shows a Dühring plot of a single-effect water/lithium bromide absorption chiller. The hot-water-driven chiller rejects waste heat from the absorber and the condenser to a stream of cooling water, and produces chilled water. A simulation of this chiller starts by specifying the assumptions (Table 6) and the design parameters and operating conditions at the design point (Table 7). Design parameters are the specified *UA* values and the flow regime (co/counter/crosscurrent, pool, or film) of all heat exchangers (evaporator, condenser, generator, absorber, solution heat exchanger) and the flow rate of weak solution through the solution pump.

One complete set of input operating parameters could be the design point values of the chilled- and cooling water temperatures $t_{chill\ in}$, $t_{chill\ out}$, $t_{cool\ in}$, $t_{cool\ out}$, hot-water flow rate m_{hot}, and total cooling capacity Q_e. With this information, a cycle simulation calculates the required hot-water temperatures; cooling-water flow rate; and temperatures, pressures, and concentrations at all internal state points. Some additional assumptions are made that reduce the number of unknown parameters.

With these assumptions and the design parameters and operating conditions as specified in Table 7, the cycle simulation can be conducted by solving the following set of equations:

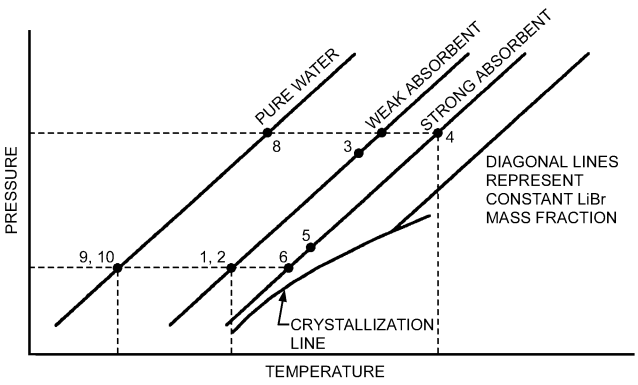

Fig. 20 Single-Effect Water/Lithium Bromide Absorption Cycle Dühring Plot

Table 6 Assumptions for Single-Effect Water/Lithium Bromide Model (Figure 20)

Assumptions
• Generator and condenser as well as evaporator and absorber are under same pressure
• Refrigerant vapor leaving evaporator is saturated pure water
• Liquid refrigerant leaving condenser is saturated
• Strong solution leaving generator is boiling
• Refrigerant vapor leaving generator has equilibrium temperature of weak solution at generator pressure
• Weak solution leaving absorber is saturated
• No liquid carryover from evaporator
• Flow restrictors are adiabatic
• Pump is isentropic
• No jacket heat losses
• LMTD (log mean temperature difference) expression adequately estimates latent changes

Table 7 Design Parameters and Operating Conditions for Single-Effect Water/Lithium Bromide Absorption Chiller

	Design Parameters	Operating Conditions
Evaporator	UA_{evap} = 319.2 kW/K, countercurrent film	$t_{chill\ in}$ = 12°C $t_{chill\ out}$ = 6°C
Condenser	UA_{cond} = 180.6 kW/K, countercurrent film	$t_{cool\ out}$ = 35°C
Absorber	UA_{abs} = 186.9 kW/K, countercurrent film-absorber	$t_{cool\ in}$ = 27°C
Generator	UA_{gen} = 143.4 kW/K, pool-generator	m_{hot} = 74.4 kg/s
Solution	UA_{sol} = 33.8 kW/K, countercurrent	
General	$\dot{m}_{weak}$ = 12 kg/s	Q_{evap} = 2148 kW

Mass Balances

$$m_{refr} + m_{strong} = m_{weak} \tag{59}$$

$$m_{strong}\xi_{strong} = m_{weak}\xi_{weak} \tag{60}$$

Energy Balances

$$\begin{aligned} Q_{evap} &= m_{refr}(h_{vapor,\,evap} - h_{liq,\,cond}) \\ &= m_{chill}(h_{chill\ in} - h_{chill\ out}) \end{aligned} \tag{61}$$

$$\begin{aligned} Q_{cond} &= m_{refr}(h_{vapor,\,gen} - h_{liq,\,cond}) \\ &= m_{cool}(h_{cool\ out} - h_{cool\ mean}) \end{aligned} \tag{62}$$

$$\begin{aligned} Q_{abs} &= m_{refr}h_{vapor,\,evap} + m_{strong}h_{strong,\,gen} \\ &\quad - m_{weak}h_{weak,\,abs} - \dot{Q}_{sol} \\ &= \dot{m}_{cool}(h_{cool\ mean} - h_{cool\ in}) \end{aligned} \tag{63}$$

$$\begin{aligned} Q_{gen} &= m_{refr}h_{vapor,\,gen} + m_{strong}h_{strong,\,gen} \\ &\quad - m_{weak}h_{weak,\,abs} - \dot{Q}_{sol} \\ &= m_{hot}(h_{hot\ in} - h_{hot\ out}) \end{aligned} \tag{64}$$

$$\begin{aligned} Q_{sol} &= m_{strong}(h_{strong,\,gen} - h_{strong,\,sol}) \\ &= m_{weak}(h_{weak,\,sol} - h_{weak,\,abs}) \end{aligned} \tag{65}$$

Table 8 Simulation Results for Single-Effect Water/Lithium Bromide Absorption Chiller

	Internal Parameters	Performance Parameters
Evaporator	$t_{vapor,evap}$ = 1.8°C $p_{sat,evap}$ = 0.697 kPa	Q_{evap} = 2148 kW m_{chill} = 85.3 kg/s
Condenser	$T_{liq,cond}$ = 46.2°C $p_{sat,cond}$ = 10.2 kPa	Q_{cond} = 2322 kW m_{cool} = 1158.7 kg/s
Absorber	ξ_{weak} = 59.6% t_{weak} = 40.7°C $t_{strong,abs}$ = 49.9°C	Q_{abs} = 2984 kW $t_{cool,mean}$ = 31.5°C
Generator	ξ_{strong} = 64.6% $t_{strong,gen}$ = 103.5°C $t_{weak,gen}$ = 92.4°C $t_{weak,sol}$ = 76.1°C	Q_{gen} = 3158 kW $t_{hot\ in}$ = 125°C $t_{hot\ out}$ = 115°C
Solution	$t_{strong,sol}$ = 62.4°C $t_{weak,sol}$ = 76.1°C	Q_{sol} = 825 kW ε = 65.4%
General	m_{vapor} = 0.93 kg/s m_{strong} = 11.06 kg/s	COP = 0.68

Heat Transfer Equations

$$Q_{evap} = UA_{evap}\frac{t_{chill\ in} - t_{chill\ out}}{\ln\left(\dfrac{t_{chill\ in} - t_{vapor,\,evap}}{t_{chill\ out} - t_{vapor,\,evap}}\right)} \tag{66}$$

$$Q_{cond} = UA_{cond}\frac{t_{cool\ out} - t_{cool\ mean}}{\ln\left(\dfrac{t_{liq,\,cond} - t_{cool\ mean}}{t_{liq,\,cond} - t_{cool\ out}}\right)} \tag{67}$$

$$Q_{abs} = UA_{abs}\frac{(t_{strong,\,abs} - t_{cool\ mean}) - (t_{weak,\,abs} - t_{cool\ in})}{\ln\left(\dfrac{t_{strong,\,abs} - t_{cool\ mean}}{t_{weak,\,abs} - t_{cool\ in}}\right)} \tag{68}$$

$$Q_{gen} = UA_{gen}\frac{(t_{hot\ in} - t_{strong,\,gen}) - (t_{hot\ out} - t_{weak,\,gen})}{\ln\left(\dfrac{t_{hot\ in} - t_{strong,\,gen}}{t_{hot\ out} - t_{weak,\,gen}}\right)} \tag{69}$$

$$Q_{sol} = UA_{sol}\frac{(t_{strong,\,gen} - t_{weak,\,sol}) - (t_{strong,\,sol} - t_{weak,\,abs})}{\ln\left(\dfrac{t_{strong,\,gen} - t_{weak,\,sol}}{t_{strong,\,sol} - t_{weak,\,abs}}\right)} \tag{70}$$

Fluid Property Equations at Each State Point

Thermal Equations of State: $h_{water}(t,p)$, $h_{sol}(t,p,\xi)$

Two-Phase Equilibrium: $t_{water,\,sat}(p)$, $t_{sol,\,sat}(p,\xi)$

The results are listed in Table 8.

A baseline correlation for the thermodynamic data of the H_2O/LiBr absorption working pair is presented in Hellman and Grossman (1996). Thermophysical property measurements at higher temperatures are reported by Feuerecker et al. (1993).

Additional high-temperature measurements of vapor pressure and specific heat appear in Langeliers et al. (2003), including correlations of the data.

The *UA* values in Equations (66) to (70) account for the actual heat and mass transfer processes, which depend greatly on operating

Table 9 Inputs and Assumptions for Double-Effect Water-Lithium Bromide Model (Figure 21)

Inputs		
Capacity	$\dot{Q}_{evap}$	1760 kW
Evaporator temperature	t_{10}	5.1°C
Desorber solution exit temperature	t_{14}	170.7°C
Condenser/absorber low temperature	t_1, t_8	42.4°C
Solution heat exchanger effectiveness	ε	0.6

Assumptions

- Steady state
- Refrigerant is pure water
- No pressure changes except through flow restrictors and pump
- State points at 1, 4, 8, 11, 14, and 18 are saturated liquid
- State point 10 is saturated vapor
- Temperature difference between high-temperature condenser and low-temperature generator is 5 K
- Parallel flow
- Both solution heat exchangers have same effectiveness
- Upper loop solution flow rate is selected such that upper condenser heat exactly matches lower generator heat requirement
- Flow restrictors are adiabatic
- Pumps are isentropic
- No jacket heat losses
- No liquid carryover from evaporator to absorber
- Vapor leaving both generators is at equilibrium temperature of entering solution stream

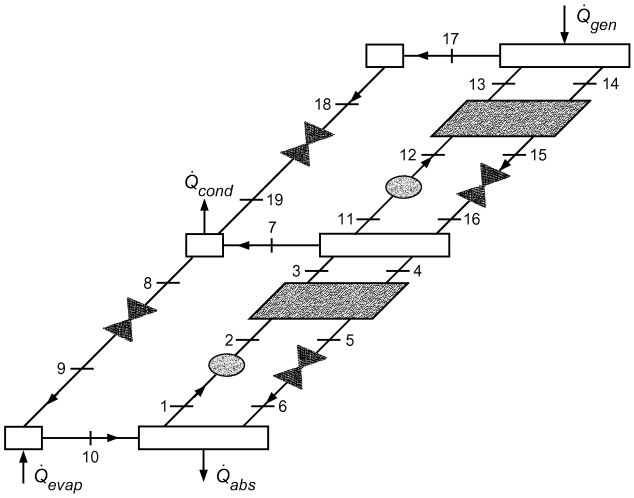

Fig. 21 Double-Effect Water/Lithium Bromide Absorption Cycle with State Points

conditions and actual heat exchanger designs. Determining these values is beyond the scope of this chapter.

Double-Effect Cycle

Double-effect cycle calculations can be performed in a manner similar to that for the single-effect cycle. Mass and energy balances of the model shown in Figure 21 were calculated using the inputs and assumptions listed in Table 9. The results are shown in Table 10. The COP is quite sensitive to several inputs and assumptions. In particular, the effectiveness of the solution heat exchangers and the driving temperature difference between the high-temperature condenser and the low-temperature generator influence the COP strongly.

Table 10 State Point Data for Double-Effect Lithium Bromide/Water Cycle of Figure 21

Point	h, kJ/kg	m, kg/s	p, kPa	Q, Fraction	t, °C	x, % LiBr

3.8 AMMONIA/WATER ABSORPTION CYCLES

Ammonia/water absorption cycles are similar to water/lithium bromide cycles, but with some important differences because of ammonia's lower latent heat compared to water, the volatility of the absorbent, and the different pressure and solubility ranges. Ammonia's latent heat is only about half that of water, so, for the same duty, the refrigerant and absorbent mass circulation rates are roughly double that of water/lithium bromide. As a result, the sensible heat loss associated with heat exchanger approaches is greater. Accordingly, ammonia/water cycles incorporate more techniques to reclaim sensible heat, described in Hanna et al. (1995). The refrigerant heat exchanger (RHX), also known as refrigerant subcooler, which improves COP by about 8%, is the most important (Holldorff 1979). Next is the absorber heat exchanger (AHX), accompanied by a generator heat exchanger (GHX) (Phillips 1976). These either replace or supplement the traditional solution heat exchanger (SHX). These components would also benefit the water/lithium bromide cycle, except that the deep vacuum in that cycle makes them impractical there.

The volatility of the water absorbent is also key. It makes the distinction between crosscurrent, cocurrent, and countercurrent mass exchange more important in all of the latent heat exchangers (Briggs 1971). It also requires a distillation column on the high-pressure side. When improperly implemented, this column can impose both cost and COP penalties. Those penalties are avoided by refluxing the column from an internal diabatic section [e.g., solution-cooled rectifier (SCR)] rather than with an external reflux pump.

The high-pressure operating regime makes it impractical to achieve multieffect performance via pressure staging. On the other hand, the exceptionally wide solubility field facilitates concentration staging. The generator-absorber heat exchange (GAX) cycle is

Licensed for single user. © 2021 ASHRAE, Inc.

Table 11 Inputs and Assumptions for Single-Effect Ammonia/Water Cycle (Figure 22)

Inputs		
Capacity	Q_{evap}	1760 kW
High-side pressure	p_{high}	1461 kPa
Low-side pressure	p_{low}	515 kPa
Absorber exit temperature	t_1	40.6°C
Generator exit temperature	t_4	95°C
Rectifier vapor exit temperature	t_7	55°C
Solution heat exchanger effectiveness	ε_{shx}	0.692
Refrigerant heat exchanger effectiveness	ε_{rhx}	0.629

Assumptions

- Steady state
- No pressure changes except through flow restrictors and pump
- States at points 1, 4, 8, 11, and 14 are saturated liquid
- States at point 12 and 13 are saturated vapor
- Flow restrictors are adiabatic
- Pump is isentropic
- No jacket heat losses
- No liquid carryover from evaporator to absorber
- Vapor leaving generator is at equilibrium temperature of entering solution stream

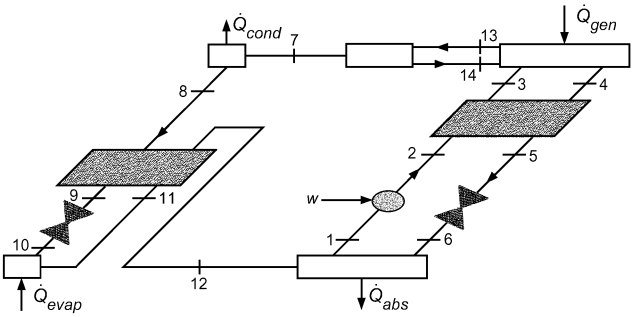

Fig. 22 Single-Effect Ammonia/Water Absorption Cycle

an especially advantageous embodiment of concentration staging (Modahl and Hayes 1988).

Ammonia/water cycles can equal the performance of water/lithium bromide cycles. The single-effect or basic GAX cycle yields the same performance as a single-effect water/lithium bromide cycle; the branched GAX cycle (Herold et al. 1991) yields the same performance as a water/lithium bromide double-effect cycle; and the VX GAX cycle (Erickson and Rane 1994) yields the same performance as a water/lithium bromide triple-effect cycle. Additional advantages of the ammonia/water cycle include refrigeration capability, air-cooling capability, all mild steel construction, extreme compactness, and capability of direct integration into industrial processes. Between heat-activated refrigerators, gas-fired residential air conditioners, and large industrial refrigeration plants, this technology has accounted for the vast majority of absorption activity over the past century.

Figure 22 shows the diagram of a typical single-effect ammonia-water absorption cycle. The inputs and assumptions in Table 11 are used to calculate a single-cycle solution, which is summarized in Table 12.

Comprehensive correlations of the thermodynamic properties of the ammonia/water absorption working pair are found in Ibrahim and Klein (1993) and Tillner-Roth and Friend (1998a, 1998b), both of which are available as commercial software. Figure 33 in Chapter 30 of this volume was prepared using the Ibrahim and Klein correlation, which is also incorporated in REFPROP (National Institute of Standards and Technology). Transport properties for ammonia/water mixtures are available in IIR (1994) and in Melinder (1998).

4. ADSORPTION REFRIGERATION SYSTEMS

Adsorption is the term frequently used for solid-vapor sorption systems in which the sorbent is a solid and the sorbate a gas. Although solid-vapor sorption systems actually comprise adsorption, absorption, and chemisorption, the term **adsorption** is often used to contrast these systems with liquid/vapor systems, such as lithium bromide/water and ammonia/water sorption pairs.

Solid/vapor sorption media can be divided into two classes:

- Bivariant systems thermodynamically behave identically to liquid/vapor systems, in which the two components [sorbent and sorbate (i.e., refrigerant)] define a thermodynamic equilibrium relation where vapor pressure, temperature, and refrigerant concentration are interrelated. These systems are commonly depicted in *p-T-x* or Dühring plots.
- Monovariant systems thermodynamically behave like a single component substance, in which vapor pressure and temperature are interrelated via a traditional Clausius-Clapeyron relation, but are independent of refrigerant concentration within a certain refrigerant concentration range. These systems are often depicted in *p-T-n* or van't Hoff plots, in which each line represents a refrigerant concentration range.

Typical examples of bivariant adsorption systems are zeolites, activated carbons, and silica gels. The most common examples of monovariant systems are metal hydrides and coordinative complex compounds (including ammoniated and hydrated complex compounds).

Practical ammonia or water refrigerant uptake concentrations for bivariant materials are typically lower than observed with their liquid vapor counterparts. Monovariant metal hydrides use hydrogen as the gaseous components. Although uptake concentrations are very low (typically in the single-digit mass percentage), the heat of

Licensed for single user. © 2021 ASHRAE, Inc.

reaction for metal hydrides is very high, yielding an overall energy density almost comparable to other solid/vapor sorption systems. Coordinative complex compounds can have refrigerant uptake that exceeds the capability of other solid/gas systems. The concentration range within which temperature and vapor pressure are independent of the refrigerant concentration can exceed 50%; the heat of sorption is distinctively higher than for bivariant solid/gas and liquid/vapor systems, but much lower than observed with most metal hydrides. The large refrigerant concentration range of constant vapor pressure, also referred to as the **coordination sphere**, lends itself to thermal energy storage applications.

The most common coordinative complex compounds are ammoniated compounds using alkali, alkali/earth, or transition metal halides (e.g., strontium chloride, calcium chloride, calcium bromide).

Although solid/vapor systems are designed to use solid sorbents and therefore do not carry the operational risk of equipment failure caused by solidifying from a liquid (as is the case with lithium bromide), some systems, particularly complex compounds, might melt at certain temperature/pressure/concentration conditions, which can lead to irreparable equipment failure.

Refrigeration or heat pump cycles constructed with solid/vapor systems are inherently batch-type cycles in which exothermic adsorption of refrigerant is followed by typically heat-actuated endothermic desorption of refrigerant. To obtain continuous refrigeration or heating, two or more solid sorbent pressure vessels (sorbers) need to operate at the same time and out of time sequence. The advantage of such cycles compared to liquid/vapor cycles is the fact that they do not require a solution makeup circuit with a solution pump; the disadvantage is the fact that the sorbent is firmly packed or situated in heat exchange hardware, inducing a higher thermal mass and requiring more involved means for recuperation.

Advanced cycles with internal heat recovery, pressure staging, and temperature staging exist for solid/vapor systems similar to liquid/vapor system. For more information, see Alefeld and Radermacher (1994).

4.1 SYMBOLS

c_p = specific heat at constant pressure, kJ/(kg·K)
COP = coefficient of performance
g = local acceleration of gravity, m/s^2
h = enthalpy, kJ/kg
I = irreversibility, kJ/K
I = irreversibility rate, kW/K
m = mass, kg
$\dot{m}$ = mass flow, kg/s
p = pressure, kPa
Q = heat energy, kJ
$\dot{Q}$ = rate of heat flow, kJ/s
R = ideal gas constant, (kPa·m^3)/(kg·K)
s = specific entropy, kJ/(kg·K)
S = total entropy, kJ/K
t = temperature, °C
T = absolute temperature, K
u = internal energy, kJ/kg
v = specific volume, m^3/kg
V = velocity of fluid, m/s
W = mechanical or shaft work, kJ
$\dot{W}$ = rate of work, power, kW
x = mass fraction (of either lithium bromide or ammonia)
x = vapor quality (fraction)
z = elevation above horizontal reference plane, m
Z = compressibility factor
Δt = temperature difference, K
ε = heat exchanger effectiveness
η = efficiency
ξ = solution concentration
ρ = density, kg/m^3

Subscripts

abs = absorber
cg = condenser to generator
cond = condenser or cooling mode
evap = evaporator
fg = fluid to vapor
gen = generator
liq = liquid
gh = high-temperature generator
o, 0 = reference conditions, usually ambient
p = pump
R = refrigerating or evaporator conditions
r = rectifier
refr = refrigerant
rhx = refrigerant heat exchanger
sat = saturated
shx = solution heat exchanger
sol = solution

CHAPTER 3

FLUID FLOW

Fluid Properties 3.1
Basic Relations of Fluid Dynamics 3.2
Basic Flow Processes 3.3
Flow Analysis 3.6
Noise in Fluid Flow 3.14
Symbols 3.14

FLOWING fluids in HVAC&R systems can transfer heat, mass, and momentum. This chapter introduces the basics of fluid mechanics related to HVAC processes, reviews pertinent flow processes, and presents a general discussion of single-phase fluid flow analysis.

1. FLUID PROPERTIES

Solids and fluids react differently to shear stress: solids deform only a finite amount, whereas fluids deform continuously until the stress is removed. Both liquids and gases are fluids, although the natures of their molecular interactions differ strongly in both degree of compressibility and formation of a free surface (interface) in liquid. In general, liquids are considered incompressible fluids; gases may range from **compressible** to nearly **incompressible**. Liquids have unbalanced molecular cohesive forces at or near the surface (interface), so the liquid surface tends to contract and has properties similar to a stretched elastic membrane. A liquid surface, therefore, is under tension (**surface tension**).

Fluid motion can be described by several simplified models. The simplest is the **ideal-fluid** model, which assumes that the fluid has no resistance to shearing. Ideal fluid flow analysis is well developed [e.g., Schlichting (1979)], and may be valid for a wide range of applications.

Viscosity is a measure of a fluid's resistance to shear. Viscous effects are taken into account by categorizing a fluid as either Newtonian or non-Newtonian. In **Newtonian fluids**, the rate of deformation is directly proportional to the shearing stress; most fluids in the HVAC industry (e.g., water, air, most refrigerants) can be treated as Newtonian. In **non-Newtonian fluids**, the relationship between the rate of deformation and shear stress is more complicated.

Density

The density ρ of a fluid is its mass per unit volume. The densities of air and water (Fox et al. 2004) at standard indoor conditions of 20°C and 101.325 kPa (sea-level atmospheric pressure) are

$$\rho_{water} = 998 \text{ kg/m}^3$$

$$\rho_{air} = 1.21 \text{ kg/m}^3$$

Viscosity

Viscosity is the resistance of adjacent fluid layers to shear. A classic example of shear is shown in Figure 1, where a fluid is between two parallel plates, each of area A separated by distance Y. The bottom plate is fixed and the top plate is moving, which induces a shearing force in the fluid. For a Newtonian fluid, the tangential force F per unit area required to slide one plate with velocity V parallel to the other is proportional to V/Y:

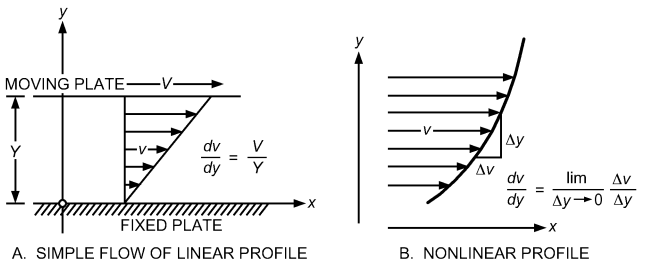

Fig. 1 Velocity Profiles and Gradients in Shear Flows

$$F/A = \mu(V/Y) \tag{1}$$

where the proportionality factor μ is the **absolute** or **dynamic viscosity** of the fluid. The ratio of F to A is the **shearing stress** τ, and V/Y is the **lateral velocity gradient** (Figure 1A). In complex flows, velocity and shear stress may vary across the flow field; this is expressed by

$$\tau = \mu \frac{dv}{dy} \tag{2}$$

The velocity gradient associated with viscous shear for a simple case involving flow velocity in the x direction but of varying magnitude in the y direction is shown in Figure 1B.

Absolute viscosity μ depends primarily on temperature. For gases (except near the critical point), viscosity increases with the square root of the absolute temperature, as predicted by the kinetic theory of gases. In contrast, a liquid's viscosity decreases as temperature increases. Absolute viscosities of various fluids are given in Chapter 33.

Absolute viscosity has dimensions of force × time/length^2. At standard indoor conditions, the absolute viscosities of water and dry air (Fox et al. 2004) are

$$\mu_{water} = 1.01 \text{ (mN·s)/m}^2$$

$$\mu_{air} = 18.1 \text{ (μN·s)/m}^2$$

Another common unit of viscosity is the **centipoise** [1 centipoise = 1 g/(s·m) = 1 mPa·s]. At standard conditions, water has a viscosity close to 1.0 centipoise.

In fluid dynamics, **kinematic viscosity** ν is sometimes used in lieu of absolute or dynamic viscosity. Kinematic viscosity is the ratio of absolute viscosity to density:

$$\nu = \mu/\rho$$

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

Copyright © 2021, ASHRAE

Licensed for single user. © 2021 ASHRAE, Inc.

At standard indoor conditions, the kinematic viscosities of water and dry air (Fox et al. 2004) are

$$\nu_{water} = 1.01 \text{ mm}^2/\text{s}$$

$$\nu_{air} = 15.0 \text{ mm}^2/\text{s}$$

The **stoke** (1 cm^2/s) and **centistoke** (1 mm^2/s) are common units for kinematic viscosity.

2. BASIC RELATIONS OF FLUID DYNAMICS

This section discusses fundamental principles of fluid flow for constant-property, homogeneous, incompressible fluids and introduces fluid dynamic considerations used in most analyses.

Continuity in a Pipe or Duct

Conservation of mass applied to fluid flow in a conduit requires that mass not be created or destroyed. Specifically, the mass flow rate into a section of pipe must equal the mass flow rate out of that section of pipe if no mass is accumulated or lost (e.g., from leakage). This requires that

$$\dot{m} = \int \rho v \, dA = \text{constant} \tag{3}$$

where $\dot{m}$ is mass flow rate across the area normal to flow, v is fluid velocity normal to differential area dA, and ρ is fluid density. Both ρ and v may vary over the cross section A of the conduit. When flow is effectively incompressible (ρ = constant) in a pipe or duct flow analysis, the **average velocity** is then $V = (1/A)\int v \, dA$, and the mass flow rate can be written as

$$\dot{m} = \rho V A \tag{4}$$

or

$$Q = \dot{m}/\rho = AV \tag{5}$$

where Q is **volumetric flow rate**.

Bernoulli Equation and Pressure Variation in Flow Direction

The **Bernoulli equation** is a fundamental principle of fluid flow analysis. It involves the conservation of momentum and energy along a streamline; it is not generally applicable across streamlines. Development is fairly straightforward. The first law of thermodynamics can apply to both mechanical flow energies (**kinetic** and **potential energy**) and thermal energies.

The change in energy content ΔE per unit mass of flowing fluid is a result of the work per unit mass w done on the system plus the heat per unit mass q absorbed or rejected:

$$\Delta E = w + q \tag{6}$$

Fluid energy is composed of kinetic, potential (because of elevation z), and internal (u) energies. Per unit mass of fluid, the energy change relation between two sections of the system is

$$\Delta\left(\frac{v^2}{2} + gz + u\right) = E_M - \Delta\left(\frac{p}{\rho}\right) + q \tag{7}$$

where the work terms are (1) external work E_M from a fluid machine (E_M is positive for a pump or blower) and (2) flow work p/ρ (where p = pressure), and g is the gravitational constant. Rearranging, the energy equation can be written as the **generalized Bernoulli equation**:

$$\Delta\left(\frac{v^2}{2} + gz + u + \frac{p}{\rho}\right) = E_M + q \tag{8}$$

The expression in parentheses in Equation (8) is the sum of the kinetic energy, potential energy, internal energy, and flow work per unit mass flow rate. In cases with no work interaction, no heat transfer, and no viscous frictional forces that convert mechanical energy into internal energy, this expression is constant and is known as the **Bernoulli constant** ***B***:

$$\frac{v^2}{2} + gz + \left(\frac{p}{\rho}\right) = B \tag{9}$$

Alternative forms of this relation are obtained through multiplication by ρ or division by g:

$$p + \frac{\rho v^2}{2} + \rho g z = \rho B \tag{10}$$

$$\frac{p}{\gamma} + \frac{v^2}{2g} + z = \frac{B}{g} \tag{11}$$

where $\gamma = \rho g$ is the **weight density** (γ = weight/volume versus ρ = mass/volume). Note that Equations (9) to (11) assume no frictional losses.

The units in the first form of the Bernoulli equation [Equation (9)] are energy per unit mass; in Equation (10), energy per unit volume; in Equation (11), energy per unit weight, usually called **head**. Note that the units for head reduce to just length [i.e., (N·m)/N to m]. In gas flow analysis, Equation (10) is often used, and $\rho g z$ is negligible. Equation (10) should be used when density variations occur. For liquid flows, Equation (11) is commonly used. Identical results are obtained with the three forms if the units are consistent and fluids are homogeneous.

Many systems of pipes, ducts, pumps, and blowers can be considered as one-dimensional flow along a streamline (i.e., variation in velocity across the pipe or duct is ignored, and local velocity v = average velocity V). When v varies significantly across the cross section, the kinetic energy term in the Bernoulli constant B is expressed as $\alpha V^2/2$, where the **kinetic energy factor** ($\alpha > 1$) expresses the ratio of the true kinetic energy of the velocity profile to that of the average velocity. For laminar flow in a wide rectangular channel, $\alpha = 1.54$, and in a pipe, $\alpha = 2.0$. For turbulent flow in a duct, $\alpha \approx 1$.

Heat transfer q may often be ignored. Conversion of mechanical energy to internal energy Δu may be expressed as a loss E_L. The change in the Bernoulli constant ($\Delta B = B_2 - B_1$) between stations 1 and 2 along the conduit can be expressed as

$$\left(\frac{p}{\rho} + \alpha\frac{V^2}{2} + gz\right)_1 + E_M - E_L = \left(\frac{p}{\rho} + \alpha\frac{V^2}{2} + gz\right)_2 \tag{12}$$

or, by dividing by g, in the form

$$\left(\frac{p}{\gamma} + \alpha\frac{V^2}{2g} + z\right)_1 + H_M - H_L = \left(\frac{p}{\gamma} + \alpha\frac{V^2}{2g} + z\right)_2 \tag{13}$$

Note that Equation (12) has units of energy per mass, whereas each term in Equation (13) has units of energy per weight, or head. The terms E_M and E_L are defined as positive, where $gH_M = E_M$ represents energy added to the conduit flow by pumps or blowers. A turbine or fluid motor thus has a negative H_M or E_M. *Note the simplicity of Equation (13)*; the total head at station 1 (pressure head plus velocity head plus elevation head) plus the head added by a

Licensed for single user. © 2021 ASHRAE, Inc.

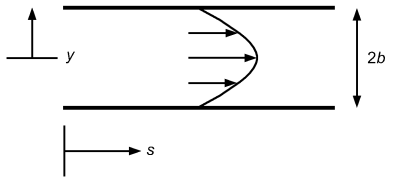

Fig. 2 Dimensions for Steady, Fully Developed Laminar Flow Equations

pump (H_M) minus the head lost through friction (H_L) is the total head at station 2.

Laminar Flow

When real-fluid effects of viscosity or turbulence are included, the continuity relation in Equation (5) is not changed, but V must be evaluated from the integral of the velocity profile, using local velocities. In fluid flow past fixed boundaries, velocity at the boundary is zero, velocity gradients exist, and shear stresses are produced. The equations of motion then become complex, and exact solutions are difficult to find except in simple cases for laminar flow between flat plates, between rotating cylinders, or within a pipe or tube.

For steady, fully developed laminar flow between two parallel plates (Figure 2), shear stress τ varies linearly with distance y from the centerline (transverse to the flow; $y = 0$ in the center of the channel). For a wide rectangular channel $2b$ tall, τ can be written as

$$\tau = \left(\frac{y}{b}\right)\tau_w = \mu\frac{dv}{dy} \tag{14}$$

where τ_w is wall shear stress $[b(dp/ds)]$, and s is flow direction. Because velocity is zero at the wall ($y = b$), Equation (14) can be integrated to yield

$$v = \left(\frac{b^2 - y^2}{2\mu}\right)\frac{dp}{ds} \tag{15}$$

The resulting parabolic velocity profile in a wide rectangular channel is commonly called **Poiseuille flow**. Maximum velocity occurs at the centerline ($y = 0$), and the average velocity V is 2/3 of the maximum velocity. From this, the longitudinal pressure drop in terms of V can be written as

$$\frac{dp}{ds} = -\left(\frac{3\mu V}{b^2}\right) \tag{16}$$

A parabolic velocity profile can also be derived for a pipe of radius R. V is 1/2 of the maximum velocity, and the pressure drop can be written as

$$\frac{dp}{ds} = -\left(\frac{8\mu V}{R^2}\right) \tag{17}$$

Turbulence

Fluid flows are generally turbulent, involving random perturbations or fluctuations of the flow (velocity and pressure), characterized by an extensive hierarchy of scales or frequencies (Robertson 1963). Flow disturbances that are not chaotic but have some degree of periodicity (e.g., the oscillating vortex trail behind bodies) have been erroneously identified as turbulence. Only flows involving random perturbations without any order or periodicity are turbulent; velocity in such a flow varies with time or locale of measurement (Figure 3).

Turbulence can be quantified statistically. The velocity most often used is the time-averaged velocity. The strength of turbulence

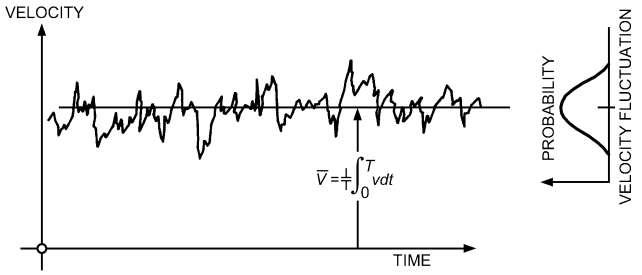

Fig. 3 Velocity Fluctuation at Point in Turbulent Flow

is characterized by the root mean square (RMS) of the instantaneous variation in velocity about this mean. Turbulence causes the fluid to transfer momentum, heat, and mass very rapidly across the flow.

Laminar and turbulent flows can be differentiated using the **Reynolds number Re**, which is a dimensionless relative ratio of inertial forces to viscous forces:

$$\mathrm{Re}_L = VL/\nu \tag{18}$$

where L is the characteristic length scale and ν is the kinematic viscosity of the fluid. In flow through pipes, tubes, and ducts, the characteristic length scale is the **hydraulic diameter D_h**, given by

$$D_h = 4A/P_w \tag{19}$$

where A is the cross-sectional area of the pipe, duct, or tube, and P_w is the wetted perimeter.

For a round pipe, D_h equals the pipe diameter. In general, **laminar flow** in pipes or ducts exists when the Reynolds number (based on D_h) is less than 2300. Fully **turbulent flow** exists when $\mathrm{Re}_{D_h} > 10\,000$. For $2300 < \mathrm{Re}_{D_h} < 10\,000$, transitional flow exists, and predictions are unreliable.

3. BASIC FLOW PROCESSES

Wall Friction

At the boundary of real-fluid flow, the relative tangential velocity at the fluid surface is zero. Sometimes in turbulent flow studies, velocity at the wall may appear finite and nonzero, implying a **fluid slip** at the wall. However, this is not the case; the conflict results from difficulty in velocity measurements near the wall (Goldstein 1938). Zero wall velocity leads to high shear stress near the wall boundary, which slows adjacent fluid layers. Thus, a velocity profile develops near a wall, with velocity increasing from zero at the wall to an exterior value within a finite lateral distance.

Laminar and turbulent flow differ significantly in their velocity profiles. Turbulent flow profiles are flat and laminar profiles are more pointed (Figure 4). As discussed, fluid velocities of the turbulent profile near the wall must drop to zero more rapidly than those of the laminar profile, so shear stress and friction are much greater in turbulent flow. Fully developed conduit flow may be characterized by the **pipe factor**, which is the ratio of average to maximum (centerline) velocity. Viscous velocity profiles result in pipe factors of 0.667 and 0.50 for wide rectangular and axisymmetric conduits. Figure 5 indicates much higher values for rectangular and circular conduits for turbulent flow. Because of the flat velocity profiles, the kinetic energy factor α in Equations (12) and (13) ranges from 1.01 to 1.10 for fully developed turbulent pipe flow.

Boundary Layer

The boundary layer is the region close to the wall where wall friction affects flow. Boundary layer thickness (usually denoted by δ) is thin compared to downstream flow distance. For external flow over a body, fluid velocity varies from zero at the wall to a maximum at

Licensed for single user. © 2021 ASHRAE, Inc.

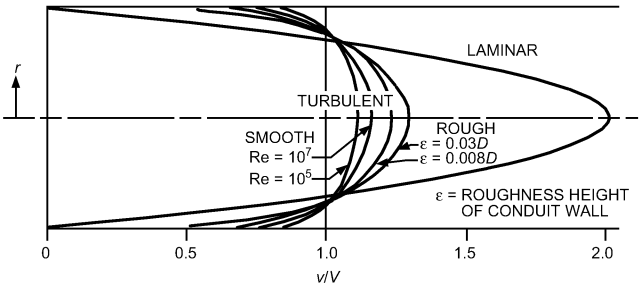

Fig. 4 Velocity Profiles of Flow in Pipes

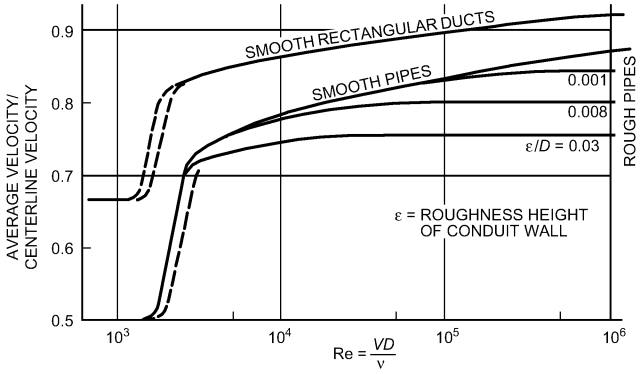

Fig. 5 Pipe Factor for Flow in Conduits

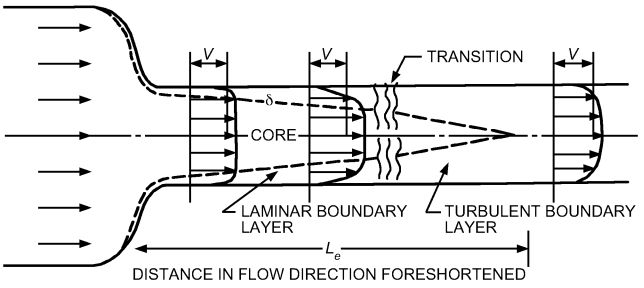

Fig. 6 Flow in Conduit Entrance Region

distance δ from the wall. Boundary layers are generally laminar near the start of their formation but may become turbulent downstream.

A significant boundary-layer occurrence exists in a pipeline or conduit following a well-rounded entrance (Figure 6). Layers grow from the walls until they meet at the center of the pipe. Near the start of the straight conduit, the layer is very thin and most likely laminar, so the uniform velocity core outside has a velocity only slightly greater than the average velocity. As the layer grows in thickness, the slower velocity near the wall requires a velocity increase in the uniform core to satisfy continuity. As flow proceeds, the wall layers grow (and centerline velocity increases) until they join, after an **entrance length L_e**. Applying the Bernoulli relation of Equation (10) to core flow indicates a decrease in pressure along the layer. Ross (1956) shows that, although the entrance length L_e is many diameters, the length in which pressure drop significantly exceeds that for fully developed flow is on the order of 10 hydraulic diameters for turbulent flow in smooth pipes.

In more general boundary-layer flows, as with wall layer development in a diffuser or for the layer developing along the surface of a strut or turning vane, pressure gradient effects can be severe and may even lead to boundary layer separation. When the outer flow velocity (v_1 in Figure 7) decreases in the flow direction, an adverse

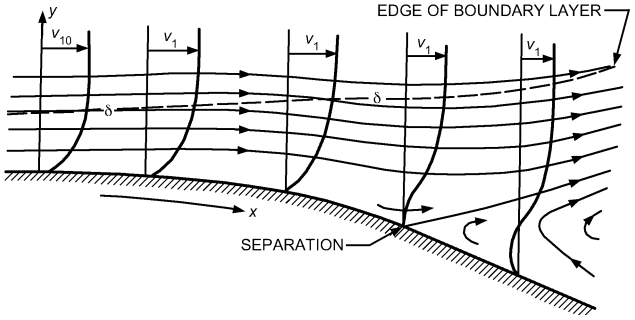

Fig. 7 Boundary Layer Flow to Separation

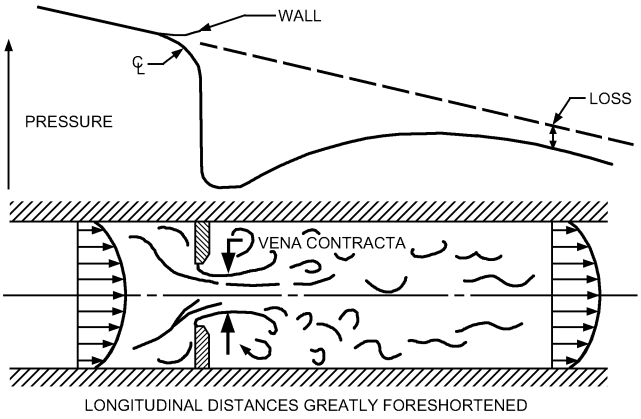

Fig. 8 Geometric Separation, Flow Development, and Loss in Flow Through Orifice

pressure gradient can cause separation, as shown in the figure. Downstream from the separation point, fluid backflows near the wall. Separation is caused by frictional velocity (thus local kinetic energy) reduction near the wall. Flow near the wall no longer has energy to move into the higher pressure imposed by the decrease in v_1 at the edge of the layer. The locale of this separation is difficult to predict, especially for the turbulent boundary layer. Analyses verify the experimental observation that a turbulent boundary layer is less subject to separation than a laminar one because of its greater kinetic energy.

Flow Patterns with Separation

In technical applications, flow with separation is common and often accepted if it is too expensive to avoid. Flow separation may be geometric or dynamic. Dynamic separation is shown in Figure 7. Geometric separation (Figures 8 and 9) results when a fluid stream passes over a very sharp corner, as with an orifice; the fluid generally leaves the corner irrespective of how much its velocity has been reduced by friction.

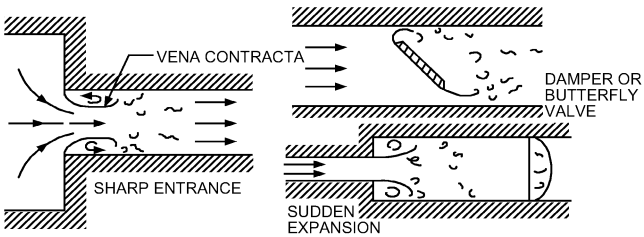

Fig. 9 Examples of Geometric Separation Encountered in Flows in Conduits

Licensed for single user. © 2021 ASHRAE, Inc.

For geometric separation in orifice flow (Figure 8), the outer streamlines separate from the sharp corners and, because of fluid inertia, contract to a section smaller than the orifice opening. The smallest section is known as the **vena contracta** and generally has a limiting area of about six-tenths of the orifice opening. After the vena contracta, the fluid stream expands rather slowly through turbulent or laminar interaction with the fluid along its sides. Outside the jet, fluid velocity is comparatively small. Turbulence helps spread out the jet, increases losses, and brings the velocity distribution back to a more uniform profile. Finally, downstream, the velocity profile returns to the fully developed flow of Figure 4. The entrance and exit profiles can profoundly affect the vena contracta and pressure drop (Coleman 2004).

Other geometric separations (Figure 9) occur in conduits at sharp entrances, inclined plates or dampers, or sudden expansions. For these geometries, a vena contracta can be identified; for sudden expansion, its area is that of the upstream contraction. Ideal-fluid theory, using free streamlines, provides insight and predicts contraction coefficients for valves, orifices, and vanes (Robertson 1965). These geometric flow separations produce large losses. To expand a flow efficiently or to have an entrance with minimum losses, design the device with gradual contours, a diffuser, or a rounded entrance.

Flow devices with gradual contours are subject to separation that is more difficult to predict, because it involves the dynamics of boundary-layer growth under an adverse pressure gradient rather than flow over a sharp corner. A diffuser is used to reduce the loss in expansion; it is possible to expand the fluid some distance at a gentle angle without difficulty, particularly if the boundary layer is turbulent. Eventually, separation may occur (Figure 10), which is frequently asymmetrical because of irregularities. Downstream flow involves flow reversal (backflow) and excess losses. Such separation is commonly called **stall** (Kline 1959). Larger expansions may use splitters that divide the diffuser into smaller sections that are less likely to have separations (Moore and Kline 1958). Another technique for controlling separation is to bleed some low-velocity fluid near the wall (Furuya et al. 1976). Alternatively, Heskested (1970) shows that suction at the corner of a sudden expansion has a strong positive effect on geometric separation.

Drag Forces on Bodies or Struts

Bodies in moving fluid streams are subjected to appreciable fluid forces or **drag**. Conventionally, the drag force F_D on a body can be expressed in terms of a **drag coefficient** C_D:

$$F_D = C_D \rho A \left(\frac{V^2}{2} \right) \tag{20}$$

where A is the projected (normal to flow) area of the body. The drag coefficient C_D is a strong function of the body's shape and angularity, and the Reynolds number of the relative flow in terms of the body's characteristic dimension.

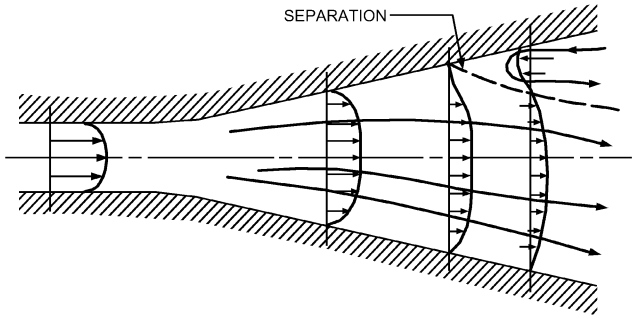

Fig. 10 Separation in Flow in Diffuser

For Reynolds numbers of 10^3 to 10^5, the C_D of most bodies is constant because of flow separation, but above 10^5, the C_D of rounded bodies drops suddenly as the surface boundary layer undergoes transition to turbulence. Typical C_D values are given in Table 1; Hoerner (1965) gives expanded values.

Nonisothermal Effects

When appreciable temperature variations exist, the primary fluid properties (density and viscosity) may no longer assumed to be constant, but vary across or along the flow. The Bernoulli equation [Equations (9) to (11)] must be used, because volumetric flow is not constant. With gas flows, the thermodynamic process involved must be considered. In general, this is assessed using Equation (9), written as

$$\int \frac{dp}{\rho} + \frac{V^2}{2} + gz = B \tag{21}$$

Effects of viscosity variations also appear. In nonisothermal laminar flow, the parabolic velocity profile (see Figure 4) is no longer valid. In general, for gases, viscosity increases with the square root of absolute temperature; for liquids, viscosity decreases with increasing temperature. This results in opposite effects.

For fully developed pipe flow, the linear variation in shear stress from the wall value τ_w to zero at the centerline is independent of the temperature gradient. In the section on Laminar Flow, τ is defined as $\tau = (y/b)\,\tau_w$, where y is the distance from the centerline and $2b$ is the wall spacing. For pipe radius $R = D/2$ and distance from the wall $y = R - r$ (Figure 11), then $\tau = \tau_w(R - y)/R$. Then, solving Equation (2) for the change in velocity yields

Table 1 Drag Coefficients

Body Shape	$10^3 < Re < 2 \times 10^5$	$Re > 3 \times 10^5$
Sphere	0.36 to 0.47	~0.1
Disk	1.12	1.12
Streamlined strut	0.1 to 0.3	< 0.1
Circular cylinder	1.0 to 1.1	0.35
Elongated rectangular strut	1.0 to 1.2	1.0 to 1.2
Square strut	~2.0	~2.0

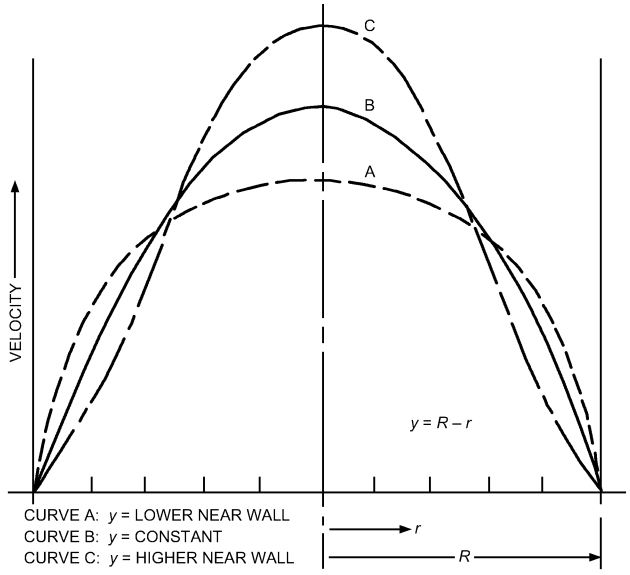

Fig. 11 Effect of Viscosity Variation on Velocity Profile of Laminar Flow in Pipe

Licensed for single user. © 2021 ASHRAE, Inc.

$$dv = \left[\frac{\tau_w (R-y)}{R\mu}\right] dy = -\left(\frac{\tau_w}{R\mu}\right) r\, dr \tag{22}$$

When fluid viscosity is lower near the wall than at the center (because of external heating of liquid or cooling of gas by heat transfer through the pipe wall), the velocity gradient is steeper near the wall and flatter near the center, so the profile is generally flattened. When liquid is cooled or gas is heated, the velocity profile is more pointed for laminar flow (Figure 11). Calculations for such flows of gases and liquid metals in pipes are in Deissler (1951). Occurrences in turbulent flow are less apparent than in laminar flow. If enough heating is applied to gaseous flows, the viscosity increase can cause reversion to laminar flow.

Buoyancy effects and the gradual approach of the fluid temperature to equilibrium with that outside the pipe can cause considerable variation in the velocity profile along the conduit. Colborne and Drobitch (1966) found the pipe factor for upward vertical flow of hot air at a Re < 2000 reduced to about 0.6 at 40 diameters from the entrance, then increased to about 0.8 at 210 diameters, and finally decreased to the isothermal value of 0.5 at the end of 320 diameters.

4. FLOW ANALYSIS

Fluid flow analysis is used to correlate pressure changes with flow rates and the nature of the conduit. For a given pipeline, either the pressure drop for a certain flow rate, or the flow rate for a certain pressure difference between the ends of the conduit, is needed. Flow analysis ultimately involves comparing a pump or blower to a conduit piping system for evaluating the expected flow rate.

Generalized Bernoulli Equation

Internal energy differences are generally small, and usually the only significant effect of heat transfer is to change the density ρ. For gas or vapor flows, use the generalized Bernoulli equation in the pressure-over-density form of Equation (12), allowing for the thermodynamic process in the pressure-density relation:

$$-\int_1^2 \frac{dp}{\rho} + \alpha_1 \frac{V_1^2}{2} + E_M = \alpha_2 \frac{V_2^2}{2} + E_L \tag{23}$$

Elevation changes involving z are often negligible and are dropped. The pressure form of Equation (10) is generally unacceptable when appreciable density variations occur, because the volumetric flow rate differs at the two stations. This is particularly serious in friction-loss evaluations where the density usually varies over considerable lengths of conduit (Benedict and Carlucci 1966). When the flow is essentially incompressible, Equation (20) is satisfactory.

Example 1. Specify a blower to produce isothermal airflow of 200 L/s through a ducting system (Figure 12). Accounting for intake and fitting losses, equivalent conduit lengths are 18 and 50 m, and flow is isothermal. Pressure at the inlet (station 1) and following the discharge (station 4), where velocity is zero, is the same. Frictional losses H_L are evaluated as 7.5 m of air between stations 1 and 2, and 72.3 m between stations 3 and 4.

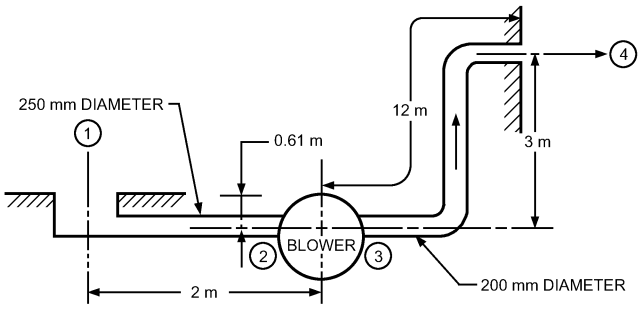

Fig. 12 Blower and Duct System for Example 1

Solution: The following form of the generalized Bernoulli relation is used in place of Equation (12), which also could be used:

$$(p_1/\rho_1 g) + \alpha_1 (V_1^2/2g) + z_1 + H_M = (p_2/\rho_2 g) + \alpha_2 (V_2^2/2g) + z_2 + H_L \tag{24}$$

The term $V_1^2/2g$ can be calculated as follows:

$$A_1 = \pi\left(\frac{D}{2}\right)^2 = \pi\left(\frac{0.250}{2}\right)^2 = 0.0491 \text{ m}^2$$

$$V_1 = Q/A_1 = \frac{0.200}{0.0491} = 4.07 \text{ m/s}$$

$$V_1^2/2g = (4.07)^2/2(9.8) = 0.846 \text{ m} \tag{25}$$

The term $V_2^2/2g$ can be calculated in a similar manner.

In Equation (24), H_M is evaluated by applying the relation between any two points on opposite sides of the blower. Because conditions at stations 1 and 4 are known, they are used, and the location-specifying subscripts on the right side of Equation (24) are changed to 4. Note that $p_1 = p_4 = p$, $\rho_1 = \rho_4 = \rho$, and $V_1 = V_4 = 0$. Thus,

$$(p/\rho g) + 0 + 0.61 + H_M = (p/\rho g) + 0 + 3 + (7.5 + 72.3) \tag{26}$$

so H_M = 82.2 m of air. For standard air (ρ = 1.20 kg/m^3), this corresponds to 970 Pa.

The pressure difference measured across the blower (between stations 2 and 3) is often taken as H_M. It can be obtained by calculating the static pressure at stations 2 and 3. Applying Equation (24) successively between stations 1 and 2 and between 3 and 4 gives

$$(p_1/\rho g) + 0 + 0.61 + 0 = (p_2/\rho g) + (1.06 \times 0.846) + 0 + 7.5$$

$$(p_3/\rho g) + (1.03 \times 2.07) + 0 + 0 = (p_4/\rho g) + 0 + 3 + 72.3 \tag{27}$$

where α just ahead of the blower is taken as 1.06, and just after the blower as 1.03; the latter value is uncertain because of possible uneven discharge from the blower. Static pressures p_1 and p_4 may be taken as zero gage. Thus,

$$p_2/\rho g = -7.8 \text{ m of air}$$

$$p_3/\rho g = 73.2 \text{ m of air} \tag{28}$$

The difference between these two numbers is 81 m, which is not the H_M calculated after Equation (24) as 82.2 m. The apparent discrepancy results from ignoring velocity at stations 2 and 3. Actually, H_M is

$$\begin{aligned} H_M &= (p_3/\rho g) + \alpha_3 (V_3^2/2g) - [(p_2/\rho g) + \alpha_2 (V_2^2/2g)] \\ &= 73.2 + (1.03 \times 2.07) - [-7.8 + (1.06 \times 0.846)] \\ &= 75.3 - (-6.9) = 82.2 \text{ m} \end{aligned} \tag{29}$$

The required blower energy is the same, no matter how it is evaluated. It is the specific energy added to the system by the machine. Only when the conduit size and velocity profiles on both sides of the machine are the same is E_M or H_M simply found from $\Delta p = p_3 - p_2$.

Conduit Friction

The loss term E_L or H_L of Equation (12) or (13) accounts for friction caused by conduit-wall shearing stresses and losses from conduit-section changes. H_L is the head loss (i.e., loss of energy per unit weight).

In real-fluid flow, a frictional shear occurs at bounding walls, gradually influencing flow further away from the boundary. A lateral velocity profile is produced and flow energy is converted into heat (fluid internal energy), which is generally unrecoverable (a loss). This loss in fully developed conduit flow is evaluated using the **Darcy-Weisbach equation**:

Licensed for single user. © 2021 ASHRAE, Inc.

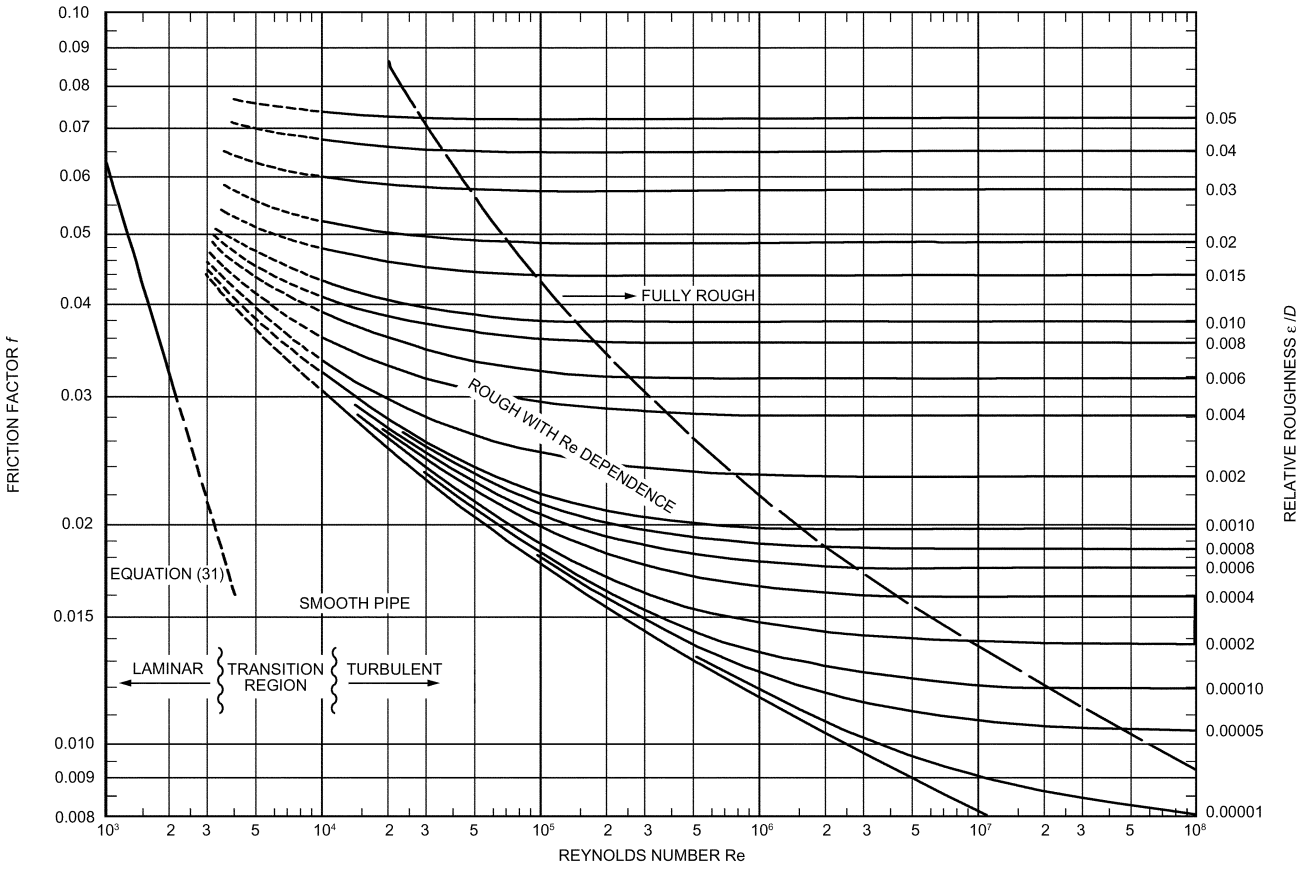

Fig. 13 Relation Between Friction Factor and Reynolds Number
(based on Moody 1944)

$$H_{L_f} = f\left(\frac{L}{D}\right)\left(\frac{V^2}{2g}\right) \tag{30}$$

where L is the length of conduit of diameter D and f is the **Darcy-Weisbach friction factor**. Sometimes a numerically different relation is used with the **Fanning friction factor** (1/4 of the Darcy friction factor f). The value of f is nearly constant for turbulent flow, varying only from about 0.01 to 0.05.

For fully developed laminar-viscous flow in a pipe, loss is evaluated from Equation (17) as follows:

$$H_{L_f} = \frac{L}{\rho g}\left(\frac{8\mu V}{R^2}\right) = \frac{32L\nu V}{D^2 g} = \frac{64}{VD/\nu}\left(\frac{L}{D}\right)\left(\frac{V^2}{2g}\right) \tag{31}$$

where $\mathrm{Re} = VD/\nu$ and $f = 64/\mathrm{Re}$. Thus, for laminar flow, the friction factor varies inversely with the Reynolds number. The value of 64/Re varies with channel shape. A good summary of shape factors is provided by Incropera and DeWitt (2002).

With turbulent flow, friction loss depends not only on flow conditions, as characterized by the Reynolds number, but also on the **roughness height** ε of the conduit wall surface. The variation is complex and is expressed in diagram form (Moody 1944), as shown in Figure 13. Historically, the Moody diagram has been used to determine friction factors, but empirical relations suitable for use in modeling programs have been developed. Most are applicable to limited ranges of Reynolds number and relative roughness. Churchill (1977) developed a relationship that is valid for all ranges of Reynolds numbers, and is more accurate than reading the Moody diagram:

$$f = 8\left[\left(\frac{8}{\mathrm{Re}_{D_h}}\right)^{12} + \frac{1}{(A+B)^{1.5}}\right]^{1/12} \tag{32a}$$

$$A = \left[2.457\ln\left(\frac{1}{\left(7/\mathrm{Re}_{D_h}\right)^{0.9} + \left(0.27\varepsilon/D_h\right)}\right)\right]^{16} \tag{32b}$$

$$B = \left(\frac{37\,530}{\mathrm{Re}_{D_h}}\right)^{16} \tag{32c}$$

Inspection of the Moody diagram indicates that, for high Reynolds numbers and relative roughness, the friction factor becomes independent of the Reynolds number in a fully rough flow or fully turbulent regime. A **transition region** from laminar to turbulent flow occurs when $2000 < \mathrm{Re} < 10\,000$. Roughness height ε, which may increase with conduit use, fouling, or aging, is usually tabulated for different types of pipes as shown in Table 2.

Noncircular Conduits. Air ducts are often rectangular in cross section. The equivalent circular conduit corresponding to the noncircular conduit must be found before the friction factor can be determined.

For turbulent flow, **hydraulic diameter D_h** is substituted for D in Equation (30) and in the Reynolds number. Noncircular duct fric-

Galvanized iron or steel	152
Cast iron	259

tion can be evaluated to within 5% for all except very extreme cross sections (e.g., tubes with deep grooves or ridges). A more refined method for finding the equivalent circular duct diameter is given in Chapter 13. With laminar flow, the loss predictions may be off by a factor as large as two.

Valve, Fitting, and Transition Losses

Valve and section changes (contractions, expansions and diffusers, elbows, bends, or tees), as well as entrances and exits, distort the fully developed velocity profiles (see Figure 4) and introduce extra flow losses that may dissipate as heat into pipelines or duct systems. Valves, for example, produce such extra losses to control the fluid flow rate. In contractions and expansions, flow separation as shown in Figures 9 and 10 causes the extra loss. The loss at rounded entrances develops as flow accelerates to higher velocities; this higher velocity near the wall leads to wall shear stresses greater than those of fully developed flow (see Figure 6). In flow around bends, velocity increases along the inner wall near the start of the bend. This increased velocity creates a secondary fluid motion in a double helical vortex pattern downstream from the bend. In all these devices, the disturbance produced locally is converted into turbulence and appears as a loss in the downstream region. The return of a disturbed flow pattern into a fully developed velocity profile may be quite slow. Ito (1962) showed that the secondary motion following a bend takes up to 100 diameters of conduit to die out but the pressure gradient settles out after 50 diameters.

In a laminar fluid flow following a rounded entrance, the **entrance length** depends on the Reynolds number:

$$L_e/D = 0.06\ \mathrm{Re} \tag{33}$$

At Re = 2000, Equation (33) shows that a length of 120 diameters is needed to establish the parabolic velocity profile. The pressure gradient reaches the developed value of Equation (30) in fewer flow diameters. The additional loss is $1.2V^2/2g$; the change in profile from uniform to parabolic results in a loss of $1.0V^2/2g$ (because $\alpha = 2.0$), and the remaining loss is caused by the excess friction. In turbulent fluid flow, only 80 to 100 diameters following the rounded entrance are needed for the velocity profile to become fully developed, but the friction loss per unit length reaches a value close to that of the fully developed flow value more quickly. After six diameters, the loss rate at a Reynolds number of 10^5 is only 14% above that of fully developed flow in the same length, whereas at 10^7, it is only 10% higher (Robertson 1963). For a sharp entrance, flow separation (see Figure 9) causes a greater disturbance, but fully developed flow is achieved in about half the length required for a rounded entrance. In a sudden expansion, the pressure change settles out in about eight times the diameter change $(D_2 - D_1)$, whereas the velocity profile may take at least a 50% greater distance to return to fully developed pipe flow (Lipstein 1962).

Instead of viewing these losses as occurring over tens or hundreds of pipe diameters, it is possible to treat the entire effect of a disturbance as if it occurs at a single point in the flow direction. By treating these losses as a local phenomenon, they can be related to the velocity by the **loss coefficient *K***:

$$\text{Loss of section} = K(V^2/2g) \tag{34}$$

Table 3 Fitting Loss Coefficients of Turbulent Flow

Fitting	Geometry	$K = \frac{\Delta P/\rho g}{V^2/2g}$
Entrance	Sharp	0.5
	Well-rounded	0.05
Contraction	Sharp ($D_2/D_1 = 0.5$)	0.38
90° elbow	Miter	1.3
	Short radius	0.90
	Long radius	0.60
	Miter with turning vanes	0.2
Globe valve	Open	10
Angle valve	Open	5
Gate valve	Open	0.19 to 0.22
	75% open	1.10
	50% open	3.6
	25% open	28.8
Any valve	Closed	∞
Tee	Straight-through flow	0.5
	Flow through branch	1.8

Chapter 22 and the *Pipe Friction Manual* (Hydraulic Institute 1990) have information for pipe applications. Chapter 21 gives information for airflow. The same type of fitting in pipes and ducts may yield a different loss, because flow disturbances are controlled by the detailed geometry of the fitting. The elbow of a small threaded pipe fitting differs from a bend in a circular duct. For 90° screw-fitting elbows, K is about 0.8 (Ito 1962), whereas smooth flanged elbows have a K as low as 0.2 at the optimum curvature.

Table 3 lists fitting loss coefficients.These values indicate losses, but there is considerable variance. Note that a well-rounded entrance yields a rather small K of 0.05, whereas a gate valve that is only 25% open yields a K of 28.8. Expansion flows, such as from one conduit size to another or at the exit into a room or reservoir, are not included. For such occurrences, the **Borda loss prediction** (from impulse-momentum considerations) is appropriate:

$$\text{Loss at expansion} = \frac{(V_1 - V_2)^2}{2g} = \frac{V_1^2}{2g}\left(1 - \frac{A_1}{A_2}\right)^2 \tag{35}$$

Expansion losses may be significantly reduced by avoiding or delaying separation using a gradual diffuser (see Figure 10). For a diffuser of about 7° total angle, the loss is only about one-sixth of the loss predicted by Equation (35). The diffuser loss for total angles above 45 to 60° exceeds that of the sudden expansion, but is moderately influenced by the diameter ratio of the expansion. Optimum diffuser design involves numerous factors; excellent performance can be achieved in short diffusers with splitter vanes or suction. Turning vanes in miter bends produce the least disturbance and loss for elbows; with careful design, the loss coefficient can be reduced to as low as 0.1.

For losses in smooth elbows, Ito (1962) found a Reynolds number effect (K slowly decreasing with increasing Re) and a minimum loss at a bend curvature (bend radius to diameter ratio) of 2.5. At this optimum curvature, a 45° turn had 63%, and a 180° turn approximately 120%, of the loss of a 90° bend. The loss does not vary linearly with the turning angle because secondary motion occurs.

Note that using K presumes its independence of the Reynolds number. Some investigators have documented a variation in the loss coefficient with the Reynolds number. Assuming that K varies with Re similarly to f, it is convenient to represent fitting losses as adding to the effective length of uniform conduit. The effective length of a fitting is then

$$L_{eff}/D = K/f_{ref} \tag{36}$$

Licensed for single user. © 2021 ASHRAE, Inc.

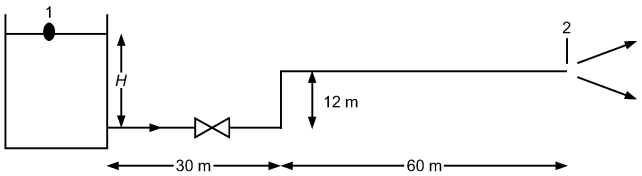

Fig. 14 Diagram for Example 2

where f_{ref} is an appropriate reference value of the friction factor. Deissler (1951) uses 0.028, and the air duct values in Chapter 21 are based on an f_{ref} of about 0.02. For rough conduits, appreciable errors can occur if the relative roughness does not correspond to that used when f_{ref} was fixed. It is unlikely that fitting losses involving separation are affected by pipe roughness. The effective length method for fitting loss evaluation is still useful.

When a conduit contains a number of section changes or fittings, the values of K are added to the fL/D friction loss, or the L_{eff}/D of the fittings are added to the conduit length L/D for evaluating the total loss H_L. This assumes that each fitting loss is fully developed and its disturbance fully smoothed out before the next section change. Such an assumption is frequently wrong, and the total loss can be overestimated. For elbow flows, the total loss of adjacent bends may be over- or underestimated. The secondary flow pattern after an elbow is such that when one follows another, perhaps in a different plane, the secondary flow of the second elbow may reinforce or partially cancel that of the first. Moving the second elbow a few diameters can reduce the total loss (from more than twice the amount) to less than the loss from one elbow. Screens or perforated plates can be used for smoothing velocity profiles (Wile 1947) and flow spreading. Their effectiveness and loss coefficients depend on their amount of open area (Baines and Peterson 1951).

Example 2. Water at 20°C flows through the piping system shown in Figure 14. Each ell has a very long radius and a loss coefficient of $K = 0.31$; the entrance at the tank is square-edged with $K = 0.5$, and the valve is a fully open globe valve with $K = 10$. The pipe roughness is 250 μm. The density $\rho = 1000$ kg/m^3 and kinematic viscosity $\nu = 1.01$ mm^2/s.

a. If pipe diameter $D = 150$ mm, what is the elevation H in the tank required to produce a flow of $Q = 60$ L/s?

Solution: Apply Equation (13) between stations 1 and 2 in the figure. Note that $p_1 = p_2$, $V_1 \approx 0$. Assume $\alpha \approx 1$. The result is

$$z_1 - z_2 = H - 12 \text{ m} = H_L + V_2^2/2g$$

From Equations (30) and (34), total pressure loss is

$$H_L = \left(\frac{fL}{D} + \sum K\right)\frac{8Q^2}{\pi^2 g D^4}$$

where $L = 102$ m, $\sum K = 0.5 + (2 \times 0.31) + 10 = 11.1$, and $V^2/2g = V_2^2/2g = 8Q^2/(\pi^2 g D^4)$. Then, substituting into Equation (13),

$$H = 12 \text{ m} + \left(1 + \frac{fL}{D} + \sum K\right)\frac{8Q^2}{\pi^2 g D^4}$$

To calculate the friction factor, first calculate Reynolds number and relative roughness:

$$\text{Re} = VD/\nu = 4Q/(\pi D\nu) = 495\,150$$

$$\varepsilon/D = 0.0017$$

From the Moody diagram or Equation (32), $f = 0.023$. Then $H_L = 15.7$ m and $H = 27.7$ m.

b. For $H = 22$ m and $D = 150$ mm, what is the flow?

Solution: Applying Equation (13) again and inserting the expression for head loss gives

$$z_1 - z_2 = 10 \text{ m} + \left(\frac{fL}{D} + \sum K + 1\right)\frac{8Q^2}{\pi^2 g D^4}$$

Because f depends on Q (unless flow is fully turbulent), iteration is required. The usual procedure is as follows:

1. Assume a value of f, usually the fully rough value for the given values of ε and D.
2. Use this value of f in the energy calculation and solve for Q.

$$Q = \sqrt{\frac{\pi^2 g D^4 (z_1 - z_2)}{8\left(\frac{fL}{D} + \sum K + 1\right)}}$$

3. Use this value of Q to recalculate Re and get a new value of f.
4. Repeat until the new and old values of f agree to two significant figures.

Iteration	f	Q, m/s	Re	f
0	0.0223	0.04737	3.98 E + 05	0.0230
1	0.0230	0.04699	3.95 E + 05	0.0230

As shown in the table, the result after two iterations is $Q \approx 0.047$ m^3/s = 47 L/s.

If the resulting flow is in the fully rough zone and the fully rough value of f is used as first guess, only one iteration is required.

c. For $H = 22$ m, what diameter pipe is needed to allow $Q = 55$ L/s?

Solution: The energy equation in part (b) must now be solved for D with Q known. This is difficult because the energy equation cannot be solved for D, even with an assumed value of f. If Churchill's expression for f is stored as a function in a calculator, program, or spreadsheet with an iterative equation solver, a solution can be generated. In this case, $D \approx 0.166$ m = 166 mm. Use the smallest available pipe size greater than 166 mm and adjust the valve as required to achieve the desired flow.

Alternatively, (1) guess an available pipe size, and (2) calculate Re, f, and H for $Q = 55$ L/s. If the resulting value of H is greater than the given value of $H = 22$ m, a larger pipe is required. If the calculated H is less than 22 m, repeat using a smaller available pipe size.

Control Valve Characterization for Liquids

Control valves are characterized by a **discharge coefficient C_d**. As long as the Reynolds number is greater than 250, the orifice equation holds for liquids:

$$Q = C_d A_o \sqrt{2\Delta p/\rho} \tag{37}$$

where A_o is the area of the orifice opening and Δp is the pressure drop across the valve. The discharge coefficient is about 0.63 for sharp-edged configurations and 0.8 to 0.9 for chamfered or rounded configurations.

Incompressible Flow in Systems

Flow devices must be evaluated in terms of their interaction with other elements of the system [e.g., the action of valves in modifying flow rate and in matching the flow-producing device (pump or blower) with the system loss]. Analysis is by the general Bernoulli equation and the loss evaluations noted previously.

A valve regulates or stops the flow of fluid by throttling. The change in flow is not proportional to the change in area of the valve opening. Figures 15 and 16 indicate the nonlinear action of valves in controlling flow. Figure 15 shows flow in a pipe discharging water from a tank that is controlled by a gate valve. The fitting loss coefficient K values are from Table 3; the friction factor f is 0.027. The degree of control also depends on the conduit L/D ratio. For a rela-

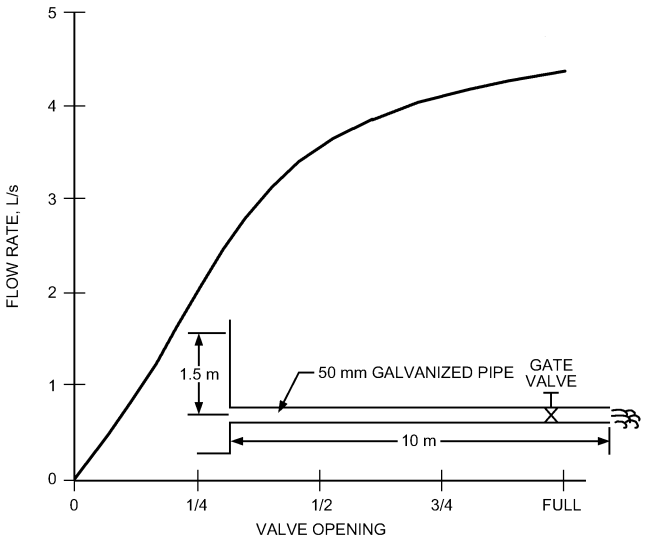

Fig. 15 Valve Action in Pipeline

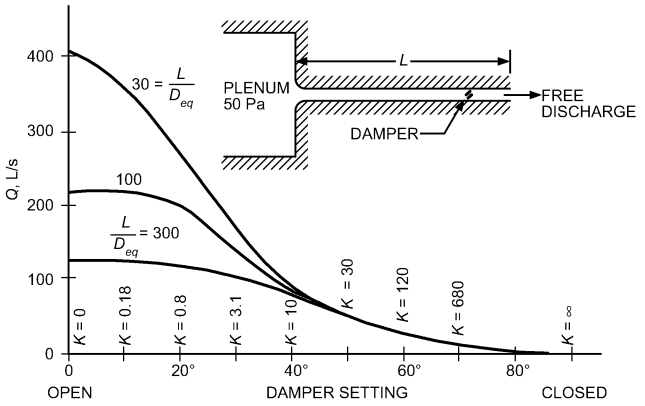

Fig. 16 Effect of Duct Length on Damper Action

tively long conduit, the valve must be nearly closed before its high K value becomes a significant portion of the loss. Figure 16 shows a control damper (essentially a butterfly valve) in a duct discharging air from a plenum held at constant pressure. With a long duct, the damper does not affect the flow rate until it is about one-quarter closed. Duct length has little effect when the damper is more than half closed. The damper closes the duct totally at the 90° position ($K = \infty$).

Flow in a system (pump or blower and conduit with fittings) involves interaction between the characteristics of the flow-producing device (pump or blower) and the loss characteristics of the pipeline or duct system. Often the devices are centrifugal, in which case the pressure produced decreases as flow increases, except for the lowest flow rates. System pressure required to overcome losses increases roughly as the square of the flow rate. The flow rate of a given system is that where the two curves of pressure versus flow rate intersect (point 1 in Figure 17). When a control valve (or damper) is partially closed, it increases losses and reduces flow (point 2 in Figure 17). For cases of constant pressure, the flow decrease caused by valving is not as great as that indicated in Figures 15 and 16.

Flow Measurement

The general principles noted (the continuity and Bernoulli equations) are basic to most fluid-metering devices. Chapter 37 has further details.

The pressure difference between the stagnation point (total pressure) and the ambient fluid stream (static pressure) is used to give a point velocity measurement. Flow rate in a conduit is measured by placing a pitot device at various locations in the cross section and spatially integrating over the velocity found. A single-point measurement may be used for approximate flow rate evaluation. When flow is fully developed, the pipe-factor information of Figure 5 can be used to estimate the flow rate from a centerline measurement. Measurements can be made in one of two modes. With the pitot-static tube, the ambient (static) pressure is found from pressure taps along the side of the forward-facing portion of the tube. When this portion is not long and slender, static pressure indication will be low and velocity indication high; as a result, a tube coefficient less than unity must be used. For parallel conduit flow, wall piezometers (taps) may take the ambient pressure, and the pitot tube indicates the impact (total pressure).

The venturi meter, flow nozzle, and orifice meter are flow-rate-metering devices based on the pressure change associated with relatively sudden changes in conduit section area (Figure 18). The elbow meter (also shown in Figure 18) is another differential pressure flowmeter. The flow nozzle is similar to the venturi in action, but does not have the downstream diffuser. For all these, the flow rate is proportional to the square root of the pressure difference resulting from fluid flow. With area-change devices (venturi, flow nozzle, and orifice meter), a theoretical flow rate relation is found by applying the Bernoulli and continuity equations in Equations (12) and (3) between stations 1 and 2:

$$Q_{theoretical} = \frac{\pi d^2}{4}\sqrt{\frac{2g\Delta h}{1-\beta^4}} \tag{38}$$

where $\Delta h = h_1 - h_2 = (p_1 - p_2)/\rho g$ and $\beta = d/D$ = ratio of throat (or orifice) diameter to conduit diameter.

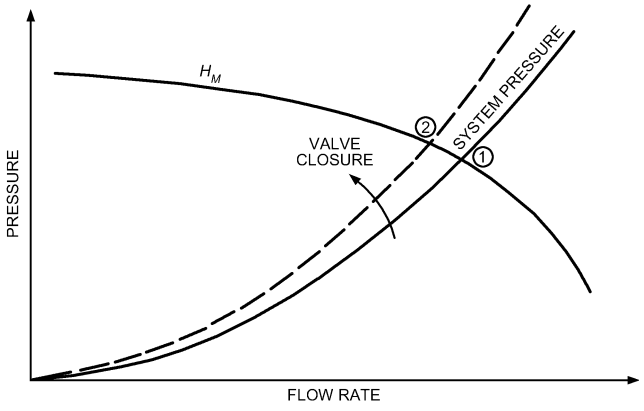

Fig. 17 Matching of Pump or Blower to System

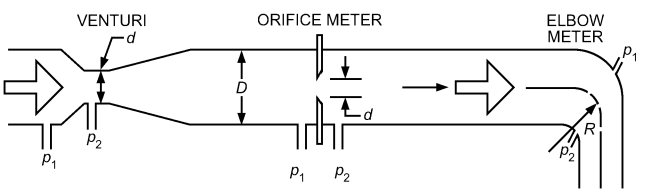

Fig. 18 Differential Pressure Flowmeters

Licensed for single user. © 2021 ASHRAE, Inc.

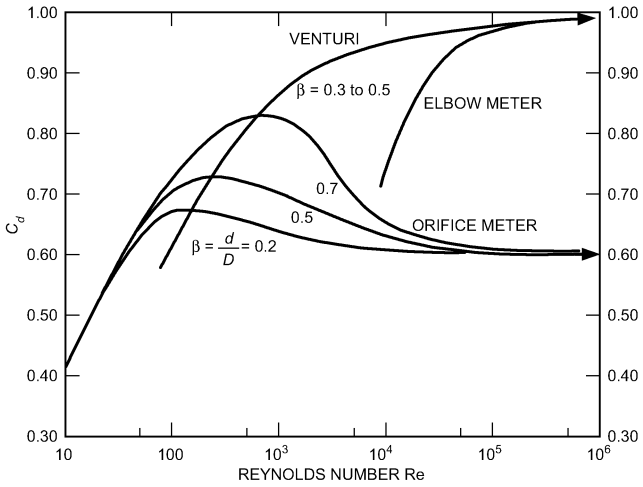

Fig. 19 Flowmeter Coefficients

The actual flow rate through the device can differ because the approach flow kinetic energy factor α deviates from unity and because of small losses. More significantly, jet contraction of orifice flow is neglected in deriving Equation (38), to the extent that it can reduce the effective flow area by a factor of 0.6. The effect of all these factors can be combined into the discharge coefficient C_d:

$$Q = C_d Q_{theoretical} \tag{39}$$

where Q is actual flow. In some sources, instead of being defined as in Equation (39), C_d is replaced with

$$\frac{C_d}{\sqrt{1-\beta^4}} \tag{40}$$

Take care to note the definition used by a source of C_d data.

The general mode of variation in C_d for orifices and venturis is indicated in Figure 19 as a function of Reynolds number and, to a lesser extent, diameter ratio β. For Reynolds numbers less than 10, the coefficient varies as $\sqrt{\text{Re}}$.

The elbow meter uses the pressure difference inside and outside the bend as the metering signal (Murdock et al. 1964). Momentum analysis gives the flow rate as

$$Q_{theoretical} = \frac{\pi d^2}{4}\sqrt{\frac{R}{2D}(2g\Delta h)} \tag{41}$$

where R is the radius of curvature of the bend. Again, a discharge coefficient C_d is needed; as in Figure 19, this drops off for lower Reynolds numbers (below 10^5). These devices are calibrated in pipes with fully developed velocity profiles, so they must be located far enough downstream of sections that modify the approach velocity.

Example 3. For a venturi with oil (ρ = 800 kg/m³, μ = 0.01 Pa·s), find Q for $P_1 - P_2$ = 28 kPa, D = 300 mm = 0.3 m, d = 150 mm = 0.15 m.

$$Q = C_d \frac{\pi d^2}{4}\sqrt{\frac{2(P_1 - P_2)}{\rho(1-\beta^4)}}$$

where β = 150 mm/300 mm = 0.5.

Inserting numbers, being careful to ensure that the units for Q are m³/s, gives $Q = 0.1527 C_d$.

Guessing $\text{Re}_D = 10^5$ and using Figure 19 gives C_d = 0.97 and Q = 0.97 × 0.962 = 0.1481 m³/s.

Checking Re_D using this Q gives Re = 5.0 × 10^5. At this Re, C_d = 0.96 and

$$Q = 0.96 \times 0.1527 = 0.147 \text{ m}^3/\text{s}$$

Unsteady Flow

Conduit flows are not always steady. In a compressible fluid, acoustic velocity is usually high and conduit length is rather short, so the time of signal travel is negligibly small. Even in the incompressible approximation, system response is not instantaneous. If a pressure difference Δp is applied between the conduit ends, the fluid mass must be accelerated and wall friction overcome, so a finite time passes before the steady flow rate corresponding to the pressure drop is achieved.

The time it takes for an incompressible fluid in a horizontal, constant-area conduit of length L to achieve steady flow may be estimated by using the unsteady flow equation of motion with wall friction effects included. On the quasi-steady assumption, friction loss is given by Equation (30); also by continuity, V is constant along the conduit. The occurrences are characterized by the relation

$$\frac{dV}{d\theta} + \left(\frac{1}{\rho}\right)\frac{dp}{ds} + \frac{fV^2}{2D} = 0 \tag{42}$$

where θ is the time and s is the distance in flow direction. Because a certain Δp is applied over conduit length L,

$$\frac{dV}{d\theta} = \frac{\Delta p}{\rho L} - \frac{fV^2}{2D} \tag{43}$$

For laminar flow, f is given by Equation (31):

$$\frac{dV}{d\theta} = \frac{\Delta p}{\rho L} - \frac{32\mu V}{\rho D^2} = A - BV \tag{44}$$

Equation (44) can be rearranged and integrated to yield the time to reach a certain velocity:

$$\theta = \int d\theta = \int \frac{dV}{A - BV} = -\frac{1}{B}\ \ln(A - BV) \tag{45}$$

and

$$V = \frac{\Delta p}{L}\left(\frac{D^2}{32\mu}\right)\left[1 - \frac{\rho L}{\Delta p}\exp\left(\frac{-32\nu\theta}{D^2}\right)\right] \tag{46}$$

For long times (θ → ∞), the steady velocity is

$$V_\infty = \frac{\Delta p}{L}\left(\frac{D^2}{32\mu}\right) = \frac{\Delta p}{L}\left(\frac{R^2}{8\mu}\right) \tag{47}$$

as given by Equation (17). Then, Equation (47) becomes

$$V = V_\infty\left[1 - \frac{\rho L}{\Delta p}\exp\left(\frac{-f_\infty V_\infty \theta}{2D}\right)\right] \tag{48}$$

where

$$f_\infty = \frac{64\nu}{V_\infty D} \tag{49}$$

The general nature of velocity development for start-up flow is derived by more complex techniques; however, the temporal variation is as given here. For shutdown flow (steady flow with $\Delta p = 0$ at θ > 0), flow decays exponentially as $e^{-\theta}$.

Turbulent flow analysis of Equation (42) also must be based on the quasi-steady approximation, with less justification. Daily et al. (1956) indicate that frictional resistance is slightly greater than the

Licensed for single user. © 2021 ASHRAE, Inc.

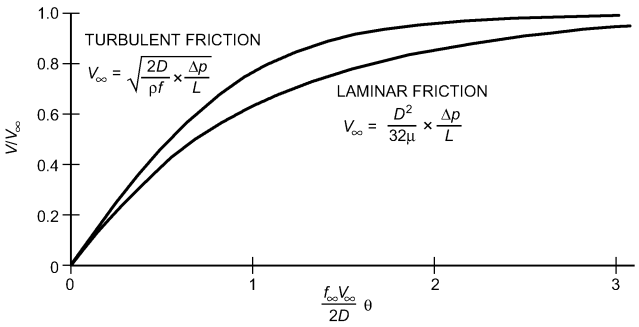

Fig. 20 Temporal Increase in Velocity Following Sudden Application of Pressure

steady-state result for accelerating flows, but appreciably less for decelerating flows. If the friction factor is approximated as constant,

$$\frac{dV}{d\theta} = \frac{\Delta p}{\rho L} - \frac{fV^2}{2D} = A - BV^2 \tag{50}$$

and for the accelerating flow,

$$\theta = \frac{1}{\sqrt{AB}} \tanh^{-1}\left(V\sqrt{\frac{B}{A}}\right) \tag{51}$$

or

$$V = \sqrt{A/B}\ \tanh(\theta\sqrt{AB}) \tag{52}$$

Because the hyperbolic tangent is zero when the independent variable is zero and unity when the variable is infinity, the initial ($V = 0$ at $\theta = 0$) and final conditions are verified. Thus, for long times ($\theta \to \infty$),

$$V_\infty = \sqrt{A/B} = \sqrt{\frac{\Delta p/\rho L}{f_\infty/2D}} = \sqrt{\frac{\Delta p}{\rho L}\left(\frac{2D}{f_\infty}\right)} \tag{53}$$

which is in accord with Equation (30) when f is constant (the flow regime is the fully rough one of Figure 13). The temporal velocity variation is then

$$V = V_\infty \tanh\left(f_\infty V_\infty \theta/2D\right) \tag{54}$$

In Figure 20, the turbulent velocity start-up result is compared with the laminar one, where initially the turbulent is steeper but of the same general form, increasing rapidly at the start but reaching V_∞ asymptotically.

Compressibility

All fluids are compressible to some degree; their density depends somewhat on the pressure. Steady liquid flow may ordinarily be treated as incompressible, and incompressible flow analysis is satisfactory for gases and vapors at velocities below about 20 to 40 m/s, except in long conduits.

For liquids in pipelines, a severe pressure surge or water hammer may be produced if flow is suddenly stopped. This pressure surge travels along the pipe at the speed of sound in the liquid, alternately compressing and decompressing the liquid. For steady gas flows in long conduits, the pressure drop along the conduit can reduce gas density enough to increase the velocity. If the conduit is long enough, the velocity may reach the speed of sound, and the Mach number (ratio of flow velocity to the speed of sound) must be considered.

Some compressible flows occur without heat gain or loss (adiabatically). If there is no friction (conversion of flow mechanical energy into internal energy), the process is reversible (isentropic) and follows the relationship

$$p/\rho^k = \text{constant}$$
$$k = c_p/c_v$$

where k, the ratio of specific heats at constant pressure and volume, is 1.4 for air and diatomic gases.

When the elevation term gz is neglected, as it is in most compressible flow analyses, the Bernoulli equation of steady flow, Equation (21), becomes

$$\int \frac{dp}{\rho} + \frac{V^2}{2} = \text{constant} \tag{55}$$

For a frictionless adiabatic process,

$$\int_1^2 \frac{dp}{\rho} = \frac{k}{k-1}\left(\frac{p_2}{\rho_2} - \frac{p_1}{\rho_1}\right) \tag{56}$$

Integrating between upstream station 1 and downstream station 2 gives

$$\frac{p_1}{\rho_1}\left(\frac{k}{k-1}\right)\left[\left(\frac{p_2}{p_1}\right)^{(k-1)/k} - 1\right] + \frac{V_2^2 - V_1^2}{2} = 0 \tag{57}$$

Equation (57) replaces the Bernoulli equation for compressible flows. If station 2 is the stagnation point at the front of a body, $V_2 = 0$, and solving Equation (57) for p_2 gives

$$p_s = p_2 = p_1\left[1 + \left(\frac{k-1}{2}\right)\frac{\rho_1 V_1^2}{kp_1}\right]^{k/(k-1)} \tag{58}$$

where p_s is the stagnation pressure.

Because the speed of sound of the gas is $a = kp/\rho$ and Mach number $M = V/a$, the stagnation pressure in Equation (58) becomes

$$p_s = p_1\left[1 + \left(\frac{k-1}{2}\right)M_1^2\right]^{k/(k-1)} \tag{59}$$

For Mach numbers less than one,

$$p_s = p_1\frac{\rho_1 V_1^2}{2}\left[1 + \frac{M_1}{4} + \left(\frac{2-k}{24}\right)M_1^4 + \cdots\right] \tag{60}$$

When $M = 0$, Equation (60) reduces to the incompressible flow result obtained from Equation (9). When the upstream Mach number exceeds 0.2, the difference is significant. Thus, a pitot tube in air is influenced by compressibility at velocities over about 66 m/s.

Flow Measurement. For isentropic flow through a converging conduit such as a flow nozzle, venturi, or orifice meter, where velocity at the upstream station 1 is small, Equation (57) gives

$$V_2 = \sqrt{\frac{2k}{k-1}\left(\frac{p_1}{\rho_1}\right)\left[1 - \left(\frac{p_2}{p_1}\right)^{(k-1)/k}\right]} \tag{61}$$

The mass flow rate is

Licensed for single user. © 2021 ASHRAE, Inc.

$$\dot{m} = V_2 A_2 \rho_2 = A_2 \sqrt{\frac{2k}{k-1}(p_1\rho_1)\left[\left(\frac{p_2}{p_1}\right)^{2/k} - \left(\frac{p_2}{p_1}\right)^{(k+1)/k}\right]} \quad (62)$$

For incompressible frictionless flow, the mass flow rate is

$$\dot{m}_{in} = A_2 \rho \sqrt{2\Delta p/\rho} = A_2 \sqrt{2\rho(p_1 - p_2)} \quad (63)$$

The compressibility effect is often accounted for by the **expansion factor** Y:

$$\dot{m} = Y\dot{m}_{in} = A_2 Y \sqrt{2\rho(p_1 - p_2)} \quad (64)$$

where $\rho = \rho_1$, and A_2 is the throat cross-sectional area. $Y \leq 1$, with $Y = 1$ for the incompressible case. For compressible flow through orifices (ISO *Standard* 5167),

$$Y = 1 - (0.351 + 0.256\beta^4 + 0.93\beta^8)(1 - (p_2/p_1)^{1/k}) \quad (65)$$

where $\beta = D_2/D_1$. For venturis and nozzles (ISO *Standard* 5167),

$$Y = \sqrt{\frac{k}{k-1}\left(\frac{p_2}{p_1}\right)^{\frac{2}{k}} \times \frac{1-\beta^4}{1-\beta^4\left(\frac{p_2}{p_1}\right)^{\frac{2}{k}}} \times \frac{1-\left(\frac{p_2}{p_1}\right)^{\frac{k-1}{k}}}{1-\left(\frac{p_2}{p_1}\right)}} \quad (66)$$

For air ($k = 1.4$), $Y = 0.95$ for an orifice with $p_2/p_1 = 0.83$ and for a venturi at about 0.90, when these devices are of relatively small diameter ($D_2/D_1 < 0.5$).

As p_2/p_1 decreases, flow rate increases, but more slowly than for the incompressible case because of the nearly linear decrease in Y. However, if the downstream velocity reaches the local speed of sound, the mass flow rate becomes the value fixed by upstream pressure and density at the critical pressure ratio:

$$\left.\frac{p_2}{p_1}\right|_c = \left(\frac{2}{k+1}\right)^{k/(k-1)} = 0.53 \text{ for air} \quad (67)$$

At higher pressure ratios than critical, **choking** (no increase in flow with decrease in downstream pressure) occurs and is used in some flow control devices to avoid flow dependence on downstream conditions.

Using Equations (38) and (39) for the incompressible mass flow rate and adding the compressible expansion factor Y results in

$$\dot{m} = C_d Y \frac{\pi d^2}{4} \sqrt{\frac{2\rho\Delta p}{1-\beta^4}} \quad (68)$$

where d is throat diameter, and C_d is the discharge coefficient introduced in the Flow Measurement section. Note that C_d accounts for the effects of friction in the measuring device, and Y accounts for compressibility.

Example 4. For a venturi used to measure air ($k = 1.4$) flow, inlet pressure and temperature are 100 kPa (absolute) and 25°C. The measured pressure at the throat is 80 kPa (absolute). The inlet diameter is 100 mm, and the throat diameter is 50 mm. What is the mass flow rate? Use $C_d = 0.995$.

Solution. Using $p_2/p_1 = 80/100 = 0.8$ and $\beta = 5/10 = 0.5$ in Equation (66) gives $Y = 0.879$. In Equation (68), $d = 0.05$ m, $\Delta p = 20$ kPa, and $\rho = 1.169$ kg/m^3 at 25°C, 100 kPa. The result is $\dot{m} = 0.383$ kg/s.

Compressible Conduit Flow

When friction loss is included, as it must be except for very short conduits, incompressible flow analysis applies until the pressure drop exceeds about 10% of the initial pressure. The possibility of sonic velocities at the end of relatively long conduits limits the amount of pressure reduction achieved. For an inlet Mach number of 0.2, discharge pressure can be reduced to about 0.2 of the initial pressure; for inflow at $M = 0.5$, discharge pressure cannot be less than about $0.45p_1$ (adiabatic) or about $0.6p_1$ (isothermal).

Analysis must treat density change, as evaluated from the continuity relation in Equation (3), with frictional occurrences evaluated from wall roughness and Reynolds number correlations of incompressible flow (Binder 1944). In evaluating valve and fitting losses, consider the reduction in K caused by compressibility (Benedict and Carlucci 1966). Although the analysis differs significantly, isothermal and adiabatic flows involve essentially the same pressure variation along the conduit, up to the limiting conditions.

Cavitation

Liquid flow with gas- or vapor-filled pockets can occur if the absolute pressure is reduced to vapor pressure or less. In this case, one or more cavities form, because liquids are rarely pure enough to withstand any tensile stressing or pressures less than vapor pressure for any length of time (John and Haberman 1980; Knapp et al. 1970; Robertson and Wislicenus 1969). Robertson and Wislicenus (1969) indicate significant occurrences in various technical fields, chiefly in hydraulic equipment and turbomachines.

Initial evidence of cavitation is the collapse noise of many small bubbles that appear initially as they are carried by the flow into higher-pressure regions. The noise is not deleterious and serves as a warning of the occurrence. As flow velocity further increases or pressure decreases, the severity of cavitation increases. More bubbles appear and may join to form large fixed cavities. The space they occupy becomes large enough to modify the flow pattern and alter performance of the flow device. Collapse of cavities on or near solid boundaries becomes so frequent that, in time, the cumulative impact causes cavitational erosion of the surface or excessive vibration. As a result, pumps can lose efficiency or their parts may erode locally. Control valves may be noisy or seriously damaged by cavitation.

Cavitation in orifice and valve flow is shown in Figure 21. With high upstream pressure and a low flow rate, no cavitation occurs. As pressure is reduced or flow rate increased, the minimum pressure in the flow (in the shear layer leaving the edge of the orifice) eventually approaches vapor pressure. Turbulence in this layer causes fluctuating pressures below the mean (as in vortex cores) and small bubble-like cavities. These are carried downstream into the region of pressure regain where they collapse, either in the fluid or on the wall (Figure 21A). As pressure reduces, more vapor- or gas-filled bubbles result and coalesce into larger ones. Eventually, a single large cavity results that collapses further downstream (Figure 21B).

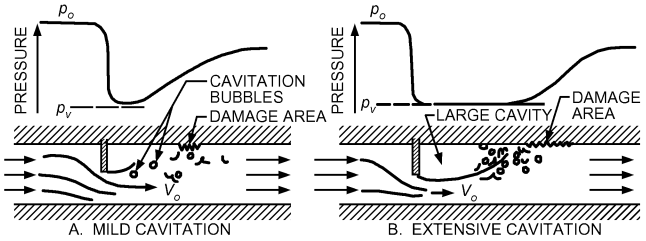

Fig. 21 Cavitation in Flows in Orifice or Valve

Licensed for single user. © 2021 ASHRAE, Inc.

The region of wall damage is then as many as 20 diameters downstream from the valve or orifice plate.

Sensitivity of a device to cavitation is measured by the **cavitation index** or **cavitation number**, which is the ratio of the available pressure above vapor pressure to the dynamic pressure of the reference flow:

$$\sigma = \frac{2(p_o - p_v)}{\rho V_o^2} \quad (69)$$

where p_v is vapor pressure, and the subscript o refers to appropriate reference conditions. Valve analyses use such an index to determine when cavitation will affect the discharge coefficient (Ball 1957). With flow-metering devices such as orifices, venturis, and flow nozzles, there is little cavitation, because it occurs mostly downstream of the flow regions involved in establishing the metering action.

The detrimental effects of cavitation can be avoided by operating the liquid-flow device at high enough pressures. When this is not possible, the flow must be changed or the device must be built to withstand cavitation effects. Some materials or surface coatings are more resistant to cavitation erosion than others, but none is immune. Surface contours can be designed to delay onset of cavitation.

5. NOISE IN FLUID FLOW

Noise in flowing fluids results from unsteady flow fields and can be at discrete frequencies or broadly distributed over the audible range. With liquid flow, cavitation results in noise through the collapse of vapor bubbles. Noise in pumps or fittings (e.g., valves) can be a rattling or sharp hissing sound, which is easily eliminated by raising the system pressure. With severe cavitation, the resulting unsteady flow can produce indirect noise from induced vibration of adjacent parts. See Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* for more information on noise control.

Disturbed laminar flow behind cylinders can be an oscillating motion. The shedding frequency f of these vortexes is characterized by a **Strouhal number** St = fd/V of about 0.21 for a circular cylinder of diameter d, over a considerable range of Reynolds numbers. This oscillating flow can be a powerful noise source, particularly when f is close to the natural frequency of the cylinder or some nearby structural member so that resonance occurs. With cylinders of another shape, such as impeller blades of a pump or blower, the characterizing Strouhal number involves the trailing-edge thickness of the member. The strength of the vortex wake, with its resulting vibrations and noise potential, can be reduced by breaking up flow with downstream splitter plates or boundary-layer trip devices (wires) on the cylinder surface.

Noises produced in pipes and ducts, especially from valves and fittings, are associated with the loss through such elements. The sound pressure of noise in water pipe flow increases linearly with pressure loss; broadband noise increases, but only in the lower-frequency range. Fitting-produced noise levels also increase with fitting loss (even without cavitation) and significantly exceed noise levels of the pipe flow. The relation between noise and loss is not surprising because both involve excessive flow perturbations. A valve's pressure-flow characteristics and structural elasticity may be such that for some operating point it oscillates, perhaps in resonance with part of the piping system, to produce excessive noise. A change in the operating point conditions or details of the valve geometry can result in significant noise reduction.

Pumps and blowers are strong potential noise sources. Turbomachinery noise is associated with blade-flow occurrences. Broadband noise appears from vortex and turbulence interaction with walls and is primarily a function of the operating point of the machine. For blowers, it has a minimum at the peak efficiency point (Groff et al. 1967). Narrow-band noise also appears at the blade-crossing frequency and its harmonics. Such noise can be very annoying because it stands out from the background. To reduce this noise, increase clearances between impeller and housing, and space impeller blades unevenly around the circumference.

6. SYMBOLS

A = area, m^2
A_o = area of orifice opening
B = Bernoulli constant
C_D = drag coefficient
C_d = discharge coefficient
D_h = hydraulic diameter
E_L = loss during conversion of energy from mechanical to internal
E_M = external work from fluid machine
F = tangential force per unit area required to slide one of two parallel plates
f = Darcy-Weisbach friction factor, or shedding frequency
F_D = drag force
f_{ref} = reference value of friction factor
g = gravitational acceleration, m/s^2
g_c = gravitational constant = 1 $(kg \cdot m)/(N \cdot s^2)$
H_L = head lost through friction
H_M = head added by pump
K = loss coefficient
k = ratio of specific heats at constant pressure and volume
L = length
L_e = entrance length
L_{eff} = effective length
$\dot{m}$ = mass flow rate
p = pressure
P_w = wetted perimeter
Q = volumetric flow rate
q = heat per unit mass absorbed or rejected
R = pipe radius
Re = Reynolds number
s = flow direction
St = Strouhal number
u = internal energy
V = velocity
v = fluid velocity normal to differential area dA
w = work per unit mass
y = distance from centerline
Y = distance between two parallel plates, m, or expansion factor
z = elevation

Greek

α = kinetic energy factor
β = d/D = ratio of throat (or orifice) diameter to conduit diameter
γ = specific mass or density
δ = boundary layer thickness
ΔE = change in energy content per unit mass of flowing fluid
Δp = pressure drop across valve
Δu = conversion of energy from mechanical to internal
ε = roughness height
θ = time
μ = proportionality factor for absolute or dynamic viscosity of fluid, $(mN \cdot s)/m^2$
ν = kinematic viscosity, mm^2/s
ρ = density, kg/m^3
σ = cavitation index or number
τ = shear stress, Pa
τ_w = wall shear stress

CHAPTER 4

HEAT TRANSFER

Heat Transfer Processes 4.1
Thermal Conduction 4.3
Thermal Radiation 4.11
Thermal Convection 4.17
Heat Exchangers 4.22
Heat Transfer Augmentation 4.24
Symbols 4.31

HEAT transfer is energy transferred because of a temperature difference. Energy moves from a higher-temperature region to a lower-temperature region by one or more of three modes: **conduction**, **radiation**, and **convection**. This chapter presents elementary principles of single-phase heat transfer, with emphasis on HVAC applications. Boiling and condensation are discussed in Chapter 5. More specific information on heat transfer to or from buildings or refrigerated spaces can be found in Chapters 14 to 19, 23, and 27 of this volume and in Chapter 24 of the 2018 *ASHRAE Handbook—Refrigeration*. Physical properties of substances can be found in Chapters 26, 28, 32, and 33 of this volume and in Chapter 19 of the 2018 *ASHRAE Handbook—Refrigeration*. Heat transfer equipment, including evaporators, condensers, heating and cooling coils, furnaces, and radiators, is covered in the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*. For further information on heat transfer, see the Bibliography.

1. HEAT TRANSFER PROCESSES

Conduction

Consider a wall that is 10 m long, 3 m tall, and 100 mm thick (Figure 1A). One side of the wall is maintained at t_{s1} = 25°C, and the other is kept at t_{s2} = 20°C. Heat transfer occurs at rate q through the wall from the warmer side to the cooler. The heat transfer mode is conduction (the only way energy can be transferred through a solid).

- If t_{s1} is raised from 25 to 30°C while everything else remains the same, q doubles because $t_{s1} - t_{s2}$ doubles.
- If the wall is twice as tall, thus doubling the area A_c of the wall, q doubles.
- If the wall is twice as thick, q is halved.

From these relationships,

$$q \propto \frac{(t_{s1} - t_{s2})A_c}{L}$$

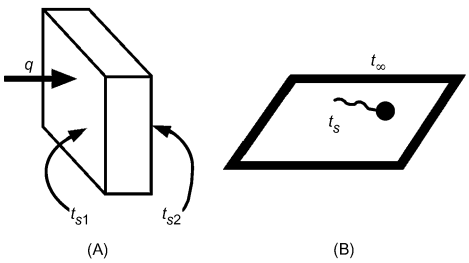

Fig. 1 (A) Conduction and (B) Convection

where ∝ means "proportional to" and L = wall thickness. However, this relation does not take wall material into account; if the wall were foam instead of concrete, q would clearly be less. The constant of proportionality is a material property, **thermal conductivity** ***k***. Thus,

$$q = k\frac{(t_{s1} - t_{s2})A_c}{L} = \frac{(t_{s1} - t_{s2})}{L/(kA_c)} \quad (1)$$

where k has units of W/(m·K). The denominator $L/(kA_c)$ can be considered the **conduction resistance** associated with the driving potential $(t_{s1} - t_{s2})$. This is analogous to current flow through an electrical resistance, $I = (V_1 - V_2)/R$, where $(V_1 - V_2)$ is driving potential, R is electrical resistance, and current I is rate of flow of charge instead of rate of heat transfer q.

Thermal resistance has units K/W. A wall with a resistance of 5 K/W requires $(t_{s1} - t_{s2})$ = 5 K for heat transfer q of 1 W. The thermal/electrical resistance analogy allows tools used to solve electrical circuits to be used for heat transfer problems.

Convection

Consider a surface at temperature t_s in contact with a fluid at t_∞ (Figure 1B). **Newton's law of cooling** expresses the rate of heat transfer from the surface of area A_s as

$$q = h_c A_s(t_s - t_\infty) = \frac{(t_s - t_\infty)}{1/(h_c A_s)} \quad (2)$$

where h_c is the **heat transfer coefficient** (Table 1) and has units of W/(m²·K). The **convection resistance** $1/(h_c A_s)$ has units of K/W.

If $t_\infty > t_s$, heat transfers from the fluid to the surface, and q is written as just $q = h_c A_s(t_\infty - t_s)$. Resistance is the same, but the sign of the temperature difference is reversed.

For heat transfer to be considered convection, fluid in contact with the surface must be in motion; if not, the mode of heat transfer is conduction. If fluid motion is caused by an external force (e.g., fan, pump, wind), it is **forced convection**. If fluid motion results from buoyant forces caused by the surface being warmer or cooler than the fluid, it is **free** (or **natural**) **convection**.

Table 1 Heat Transfer Coefficients by Convection Type

Convection Type	h_c, W/(m²·K)
Free, gases	2 to 25
Free, liquids	10 to 1000
Forced, gases	25 to 250
Forced, liquids	50 to 20 000
Boiling, condensation	2500 to 100 000

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

Radiation

Matter emits thermal radiation at its surface when its temperature is above absolute zero. This radiation is in the form of photons of varying frequency. These photons leaving the surface need no medium to transport them, unlike conduction and convection (in which heat transfer occurs through matter). The rate of thermal radiant energy emitted by a surface depends on its absolute temperature and its surface characteristics. A surface that absorbs all radiation incident upon it is called a **black surface**, and emits energy at the maximum possible rate at a given temperature. The heat emission from a black surface is given by the **Stefan-Boltzmann law:**

$$q_{emitted,\,black} = A_s W_b = A_s \sigma T_s^4$$

where $W_b = \sigma T_s^4$ is the **blackbody emissive power** in W/m^2; T_s is absolute surface temperature, K; and $\sigma = 5.67 \times 10^{-8}$ W/(m$^2 \cdot$K^4) is the Stefan-Boltzmann constant. If a surface is not black, the emission per unit time per unit area is

$$W = \varepsilon W_b = \varepsilon \sigma T_s^4$$

where W is emissive power, and ε is emissivity, where $0 \le \varepsilon \le 1$. For a black surface, $\varepsilon = 1$.

Nonblack surfaces do not absorb all incident radiation. The absorbed radiation is

$$q_{absorbed} = \alpha A_s G$$

where **absorptivity** α is the fraction of incident radiation absorbed, and **irradiation** G is the rate of radiant energy incident on a surface per unit area of the receiving surface. For a black surface, $\alpha = 1$.

A surface's emissivity and absorptivity are often both functions of the wavelength distribution of photons emitted and absorbed, respectively, by the surface. However, in many cases, it is reasonable to assume that both α and ε are independent of wavelength. If so, $\alpha = \varepsilon$ (a **gray surface**).

Two surfaces at different temperatures that can "see" each other can exchange energy through radiation. The net exchange rate depends on the surfaces' (1) relative size, (2) relative orientation and shape, (3) temperatures, and (4) emissivity and absorptivity. However, for a small area A_s in a large enclosure at constant temperature t_{surr}, the irradiation on A_s from the surroundings is the blackbody emissive power of the surroundings $W_{b,surr}$. So, if $t_s > t_{surr}$, net heat loss from gray surface A_s in the radiation exchange with the surroundings at T_{surr} is

$$\begin{aligned} q_{net} &= q_{emitted} - q_{absorbed} = \varepsilon A_s W_{bs} - \alpha A_s W_{b,surr} \\ &= \varepsilon A_s \sigma (T_s^4 - T_{surr}^4) \end{aligned} \tag{3}$$

where $\alpha = \varepsilon$ for the gray surface. If $t_s < t_{surr}$, the expression for q_{net} is the same with the sign reversed, and q_{net} is the net gain by A_s.

Note that q_{net} can be written as

$$q_{net} = \frac{W_{bs} - W_{b,surr}}{1/(\varepsilon A_s)}$$

In this form, $E_{bs} - E_{b,surr}$ is analogous to the driving potential in an electric circuit, and $1/(\varepsilon A_s)$ is analogous to electrical resistance. This is a convenient analogy when only radiation is being considered, but if convection and radiation both occur at a surface, convection is described by a driving potential based on the difference in the first power of the temperatures, whereas radiation is described by the difference in the fourth power of the temperatures. In cases like this, it is often useful to express net radiation as

$$q_{net} = h_r A_s (t_s - t_{surr}) = (t_s - t_{surr})/(1/h_r A_s) \tag{4}$$

where $h_r = \sigma\varepsilon(T_s^2 + T_{surr}^2)(T_s + T_{surr})$ is often called a **radiation heat transfer coefficient**. The disadvantage of this form is that h_r depends on t_s, which is often the desired result of the calculation.

Combined Radiation and Convection

When $t_{surr} = t_\infty$ in Equation (4), the total heat transfer from a surface by convection and radiation combined is then

$$q = q_{rad} + q_{conv} = (t_s - t_\infty) A_s (h_r + h_c)$$

The temperature difference $t_s - t_\infty$ is in either K or °C; the difference is the same. Either can be used; however, absolute temperatures *must* be used to calculate h_r. (Absolute temperatures are K = °C + 273.15.) Note that h_c and h_r are always positive, and that the direction of q is determined by the sign of $(t_s - t_\infty)$.

Contact or Interface Resistance

Heat flow through two layers encounters two conduction resistances L_1/k_1A and L_2/k_2A (Figure 2). At the interface between two layers are gaps across which heat is transferred by a combination of conduction at contact points and convection and radiation across gaps. This multimode heat transfer process is usually characterized using a contact resistance coefficient R''_{cont} or contact conductance h_{cont}.

$$q = \frac{\Delta t}{R''_{cont}/A} = h_{cont} A \Delta t$$

where Δt is the temperature drop across the interface. R''_{cont} is in (m$^2 \cdot$K)/W, and h_{cont} is in W/(m$^2 \cdot$K). The contact or interface resistance is $R_{cont} = R''_{cont}/A = 1/h_{cont}A$, and the resistance of the two layers combined is the sum of the resistances of the two layers and the contact resistance.

Contact resistance can be reduced by lowering surface roughnesses, increasing contact pressure, or using a conductive grease or paste to fill the gaps.

Heat Flux

The conduction heat transfer can be written as

$$q'' = \frac{q}{A_c} = \frac{k(t_{s1} - t_{s2})}{L}$$

where q'' is heat flux in W/m^2. Similarly, for convection the heat flux is

$$q'' = \frac{q}{A_s} = h_c (t_s - t_\infty)$$

and net heat flux from radiation at the surface is

$$q''_{net} = \frac{q_{net}}{A_s} = \varepsilon\sigma(T_s^4 - T_{surr}^4)$$

Overall Resistance and Heat Transfer Coefficient

In Equation (1) for conduction in a slab, Equation (4) for radiative heat transfer rate between two surfaces, and Equation (2) for convective heat transfer rate from a surface, the heat transfer rate is expressed as a temperature difference divided by a thermal resistance. Using the electrical resistance analogy, with temperature difference and heat transfer rate instead of potential difference and current, respectively, tools for solving series electrical resistance circuits can also be applied to heat transfer circuits. For example, consider the heat transfer rate from a liquid to the surrounding gas separated by a constant cross-sectional area solid, as shown in Figure 3. The heat transfer rate from the liquid to the adjacent surface is by convection, then across the solid body by conduction, and finally from the solid surface to the surroundings by both convection and radiation. A circuit using the equations for resistances in each mode is also shown. From the circuit, the heat transfer rate is

$$q = \frac{(t_{f1} - t_{f2})}{R_1 + R_2 + R_3}$$

where

$$R_1 = 1/hA \qquad R_2 = L/kA \qquad R_3 = \frac{(1/h_c A)(1/h_r A)}{(1/h_c A) + (1/h_r A)}$$

Resistance R_3 is the parallel combination of the convection and radiation resistances on the right-hand surface, $1/h_c A$ and $1/h_r A$. Equivalently, $R_3 = 1/h_{rc} A$, where h_{rc} on the air side is the sum of the convection and radiation heat transfer coefficients (i.e., $h_{rc} = h_c + h_r$).

The heat transfer rate can also be written as

$$q = UA(t_{f1} - t_{f2})$$

where U is the overall heat transfer coefficient that accounts for all the resistances involved. Note that

$$\frac{t_{f1} - t_{f2}}{q} = \frac{1}{UA} = R_1 + R_2 + R_3$$

The product UA is overall conductance, the reciprocal of overall resistance. The surface area A on which U is based is not always constant as in this example, and should always be specified when referring to U.

Heat transfer rates are equal from the warm liquid to the solid surface, through the solid, and then to the cool gas. Temperature drops across each part of the heat flow path are related to the resistances (as voltage drops are in an electric circuit), so that

$$t_{f1} - t_1 = qR_1 \qquad t_1 - t_2 = qR_2 \qquad t_2 - t_{f2} = qR_3$$

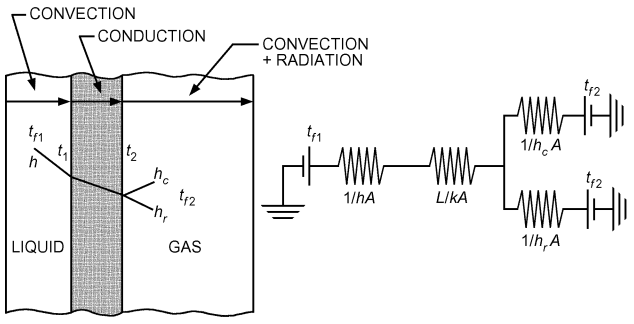

Fig. 3 Thermal Circuit

2. THERMAL CONDUCTION

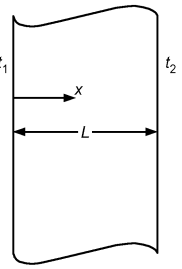
One-Dimensional Steady-State Conduction

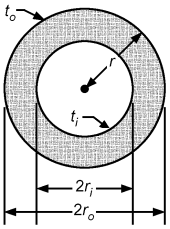
Steady-state heat transfer rates and resistances for (1) a slab of constant cross-sectional area, (2) a hollow cylinder with radial heat transfer, and (3) a hollow sphere are given in Table 2.

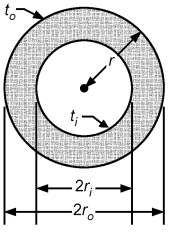
Example 1. Chilled water at 5°C flows in a copper pipe with a thermal conductivity k_p of 400 W/(m·K), with internal and external diameters of ID = 100 mm and OD = 120 mm. (Figure 4) The tube is covered with insulation 50 mm thick, with k_i = 0.20 W/(m·K). The surrounding air is at t_a = 25°C, and the heat transfer coefficient at the outer surface h_o = 10 W/(m²·K). Emissivity of the outer surface is ε = 0.85. The heat transfer coefficient inside the tube is h_i = 1000 W/(m²·K). Contact resistance between the insulation and the pipe is assumed to be negligible. Find the rate of heat gain for a given length of pipe and the temperature at the pipe-insulation interface.

Solution: The outer diameter of the insulation is D_{ins} = 120 + 2(50) = 220 mm. From Table 2, for L = 1 m,

$$R_1 = \frac{1}{h_i \pi \mathrm{ID} L} = 3.2 \times 10^{-3} \text{ K/W}$$







$$R_2 = \frac{\ln(\mathrm{OD}/\mathrm{ID})}{2\pi k_p L} = 7 \times 10^{-5} \text{ K/W}$$

$$R_3 = \frac{\ln(D_{ins}/\mathrm{OD})}{2\pi k_i L} = 0.482 \text{ K/W}$$

$$R_c = \frac{1}{h_o \pi D_{ins} L} = 0.144 \text{ K/W}$$

Assuming insulation surface temperature t_s = 21°C (i.e., 294 K) and $T_{surr} = T_a$ = 298.15 K, $h_r = \varepsilon\sigma(T_s^2 + T_{surr}^2)(T_s + T_{surr}) = 5.0$ W/(m²·K).

Table 2 One-Dimensional Conduction Shape Factors

Configuration	Heat Transfer Rate	Thermal Resistance
Constant cross-sectional area slab 	$q_x = kA_x \frac{t_1 - t_2}{L}$	$\frac{L}{kA_x}$
Hollow cylinder of length L with negligible heat transfer from end surfaces 	$q_r = \frac{2\pi kL(t_i - t_o)}{\ln\left(\frac{r_o}{r_i}\right)}$	$R = \frac{\ln(r_o/r_i)}{2\pi kL}$
Hollow sphere 	$q_r = \frac{4\pi k(t_i - t_o)}{\frac{1}{r_i} - \frac{1}{r_o}}$	$R = \frac{1/r_i - 1/r_o}{4\pi k}$

$$R_r = \frac{1}{h_r \pi D_{ins} L} = 0.288 \text{ K/W}$$

$$R_4 = \frac{R_r R_c}{R_r + R_c} = 0.096 \text{ K/W}$$

$$R_{tot} = R_1 + R_2 + R_3 + R_4 = 0.581 \text{ K/W}$$

Finally, the rate of heat gain by the cold water is

$$q_{rc} = \frac{t_a - t}{R_{tot}} = 34.4 \text{ W}$$

Temperature at the pipe/insulation interface is

$$t_{s2} = t + q_{rc}(R_1 + R_2) = 5.1°C$$

Temperature at the insulation's surface is

$$t_{s3} = t_a - q_{rc} R_4 = 21.7°C$$

which is very close to the assumed value of 22°C.

Note the importance of the pipe/insulation interface temperature. If this temperature is below the dew point, condensation will occur that will damage the insulation. A more complete version of this kind of example is given in Chapter 6. It covers calculation of interface temperatures and the vapor pressures needed to find the corresponding dew-point temperatures at the interface, as well as methods to prevent condensation.

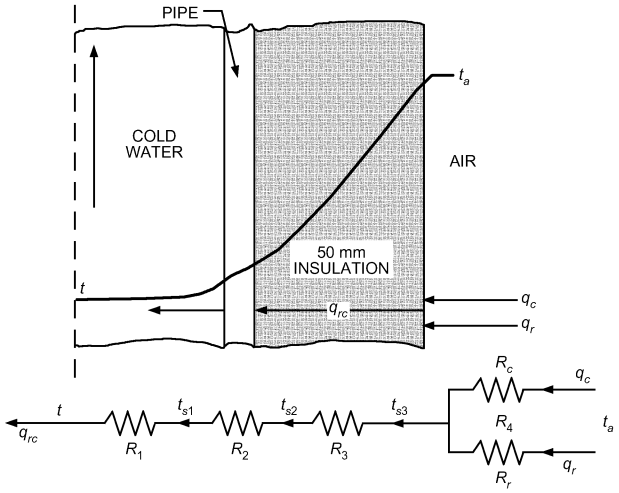


Fig. 4 Thermal Circuit Diagram for Insulated Water Pipe (Example 1)

Two- and Three-Dimensional Steady-State Conduction: Shape Factors

Mathematical solutions to a number of two and three-dimensional conduction problems are available in Carslaw and Jaeger (1959). Complex problems can also often be solved by graphical or numerical methods, as described by Adams and Rogers (1973), Croft and Lilley (1977), and Patankar (1980). There are many two- and three-dimensional steady-state cases that can be solved using conduction shape factors. Using the conduction shape factor S, the heat transfer rate is expressed as

$$q = Sk(t_1 - t_2) = (t_1 - t_2)/(1/Sk) \quad (5)$$

where k is the material's thermal conductivity, t_1 and t_2 are temperatures of two surfaces, and $1/(Sk)$ is thermal resistance. Conduction shape factors for some common configurations are given in Table 3.

Example 2. The walls and roof of a house are made of 200 mm thick concrete with k = 0.75 W/(m·K). The inner surface is at 20°C, and the outer surface is at 8°C. The roof is 10 × 10 m, and the walls are 6 m high. Find the rate of heat loss from the house through its walls and roof, including edge and corner effects.

Solution: The rate of heat transfer excluding the edges and corners is first determined:

$$A_{total} = (10 - 0.4)(10 - 0.4) + 4(10 - 0.4)(6 - 0.2) = 314.9 \text{ m}^2$$

$$q_{walls+ceiling} = \frac{kA_{total}}{L}(\Delta T) = \frac{[0.75 \text{ W/(m·K)}](314.9 \text{ m}^2)}{0.2 \text{ m}}$$
$$= (20 - 8)°C = 14\,170 \text{ W}$$

The shape factors for the corners and edges are in Table 2:

$$S_{corners+edges} = 4 \times S_{corner} + 4 \times S_{edge}$$
$$= 4 \times 0.15L + 4 \times 0.54W$$
$$= 4 \times 0.15(0.2 \text{ m}) + 4 \times 0.54(9.6 \text{ m}) = 20.86 \text{ m}$$

and the heat transfer rate is

$$q_{corners+edges} = S_{corners+edges}\, k\Delta T$$
$$= (20.86 \text{ m})[0.75 \text{ W/(m·K)}](20 - 8)°C$$
$$= 188 \text{ W}$$

which leads to

$$q_{total} = 14\,170 \text{ W} + 188 \text{ W} = 14\,358 \text{ W} = 14.4 \text{ kW}$$

Note that the edges and corners are 1.3% of the total.

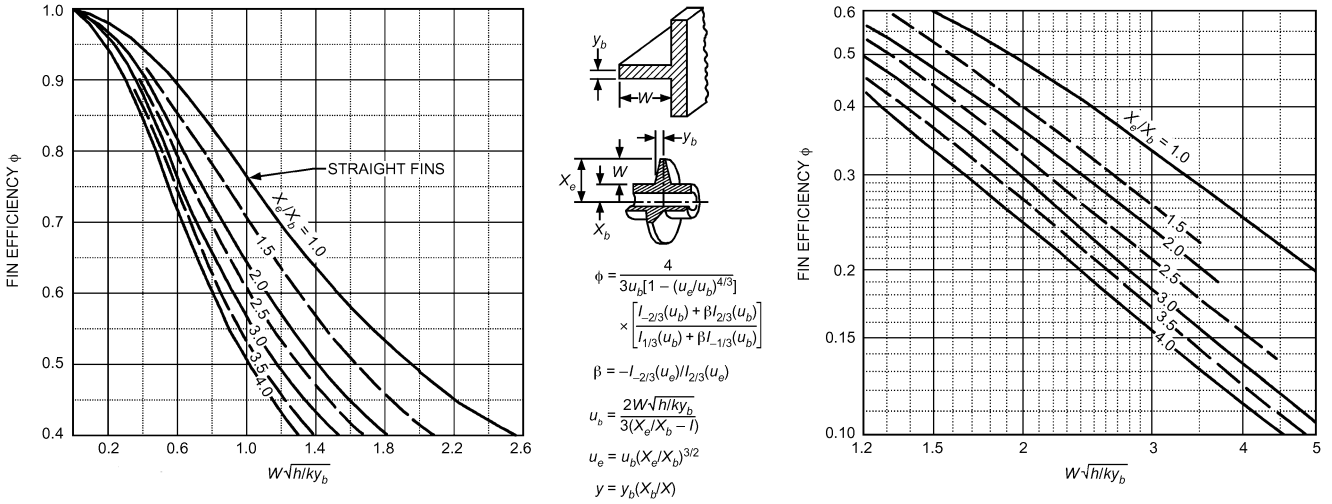

Fig. 6 Efficiency of Annular Fins with Constant Metal Area for Heat Flow

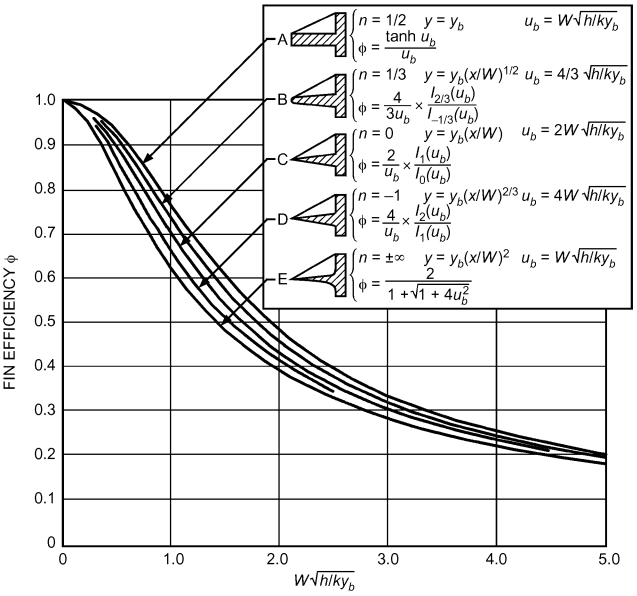

Fig. 7 Efficiency of Several Types of Straight Fins

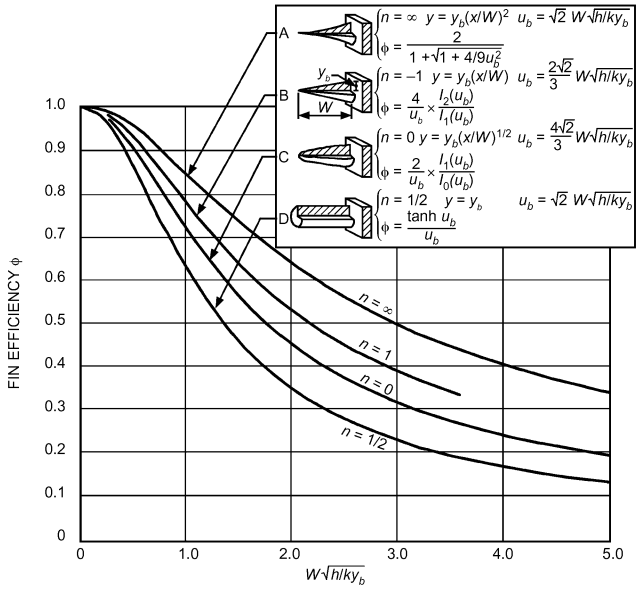

Fig. 8 Efficiency of Four Types of Spines

Extended Surfaces

Heat transfer from a surface can be increased by attaching fins or extended surfaces to increase the area available for heat transfer. A few common fin geometries are shown in Figures 5 to 8. Fins provide a large surface area in a low volume, thus lowering material costs for a given performance. To achieve optimum design, fins are generally located on the side of the heat exchanger with lower heat transfer coefficients (e.g., the air side of an air-to-water coil). Equipment with extended surfaces includes natural- and forced-convection coils and shell-and-tube evaporators and condensers. Fins are also used inside tubes in condensers and dry expansion evaporators.

Fin Efficiency. As heat flows from the root of a fin to its tip, temperature drops because of the fin material's thermal resistance. The temperature difference between the fin and surrounding fluid is therefore greater at the root than at the tip, causing a corresponding variation in heat flux. Therefore, increases in fin length result in proportionately less additional heat transfer. To account for this effect, **fin efficiency** ϕ is defined as the ratio of the actual heat transferred from the fin to the heat that would be transferred if the entire fin were at its root or base temperature:

$$\phi = \frac{q}{hA_s(t_r - t_e)} \tag{6}$$

where q is heat transfer rate into/out of the fin's root, t_e is temperature of the surrounding environment, t_r is temperature at fin root, and A_s is surface area of the fin. Fin efficiency is low for long or thin fins, or fins made of low-thermal-conductivity material. Fin efficiency decreases as the heat transfer coefficient increases because of increased heat flow. For natural convection in air-cooled condensers and evaporators, where the air-side h is low, fins can be fairly large and fabricated from low-conductivity materials such as steel instead of from copper or aluminum. For condensing and boiling, where large heat transfer coefficients are involved, fins must be very short for optimum use of material. Fin efficiencies for a few geometries are shown in Figures 5 to 8. Temperature distribution and fin efficiencies for various fin shapes are derived in most heat transfer texts.

Licensed for single user. © 2021 ASHRAE, Inc.

Constant-Area Fins and Spines. For fins or spines with constant cross-sectional area [e.g., straight fins (option A in Figure 7), cylindrical spines (option D in Figure 8)], the efficiency can be calculated as

$$\phi = \frac{\tanh(mW_c)}{mW_c} \tag{7}$$

where

m = $\sqrt{hP/kA_c}$
P = fin perimeter
A_c = fin cross-sectional area
W_c = corrected fin/spine length = $W + A_c/P$
A_c/P = $d/4$ for a cylindrical spine with diameter d
= $a/4$ for an $a \times a$ square spine
= $y_b = \delta/2$ for a straight fin with thickness δ

Empirical Expressions for Fins on Tubes. Schmidt (1949) presents approximate, but reasonably accurate, analytical expressions (for computer use) for the fin efficiency of circular, rectangular, and hexagonal arrays of fins on round tubes, as shown in Figures 5, 9, and 10, respectively. Rectangular fin arrays are used for an in-line tube arrangement in finned-tube heat exchangers, and hexagonal arrays are used for staggered tubes. Schmidt's empirical solution is given by

$$\phi = \frac{\tanh(mr_bZ)}{mr_bZ} \tag{8}$$

where r_b is tube radius, $m = \sqrt{2h/k\delta}$, δ = fin thickness, and Z is given by

$$Z = [(r_e/r_b) - 1][1 + 0.35 \ln(r_e/r_b)]$$

where r_e is the actual or equivalent fin tip radius. For **circular fins**, r_e/r_b is the actual ratio of fin tip radius to tube radius. For rectangular fins (Figure 9),

$$r_e/r_b = 1.28\,\Psi\sqrt{\beta - 0.2} \qquad \Psi = M/r_b \qquad \beta = L/M \geq 1$$

where M and L are defined by Figure 9 as $a/2$ or $b/2$, depending on which is greater. For hexagonal fins (Figure 10),

$$r_e/r_b = 1.27\,\Psi\sqrt{\beta - 0.3}$$

where Ψ and β are defined as previously, and M and L are defined by Figure 10 as $a/2$ or b (whichever is less) and $0.5\sqrt{(a/2)^2 + b^2}$, respectively.

For constant-thickness square fins on a round tube ($L = M$ in Figure 9), the efficiency of a constant-thickness annular fin of the same area can be used. For more accuracy, particularly with rectangular fins of large aspect ratio, divide the fin into circular sectors as described by Rich (1966).

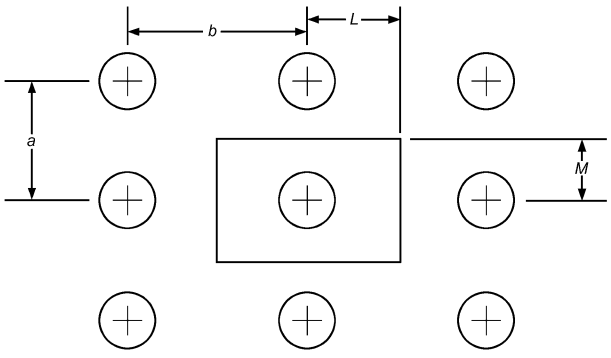

Fig. 9 Rectangular Tube Array

Other sources of information on finned surfaces are listed in the References and Bibliography.

Surface Efficiency. Heat transfer from a finned surface (e.g., a tube) that includes both fin area A_s and unfinned or prime area A_p is given by

$$q = (h_pA_p + \phi h_sA_s)(t_r - t_e) \tag{9}$$

Assuming the heat transfer coefficients for the fin and prime surfaces are equal, a **surface efficiency** ϕ_s can be derived as

$$\phi_s = \frac{A_p + \phi A_s}{A} \tag{10}$$

where $A = A_s + A_p$ is the total surface area, the sum of the fin and prime areas. The heat transfer in Equation (8) can then be written as

$$q = \phi_s hA(t_r - t_e) = \frac{t_r - t_e}{1/(\phi_s hA)} \tag{11}$$

where $1/(\phi_s hA)$ is the finned surface resistance.

Example 3. An aluminum tube with k = 186 W/(m·K), ID = 45 mm, and OD = 50 mm has circular aluminum fins δ = 1 mm thick with an outer diameter of D_{fin} = 100 mm. There are N' = 250 fins per metre of tube length. Steam condenses inside the tube at t_i = 200°C with a large heat transfer coefficient on the inner tube surface. Air at t_∞ = 25°C is heated by the steam. The heat transfer coefficient outside the tube is 40 W/(m²·K). Find the rate of heat transfer per metre of tube length.

Solution: From Figure 5's efficiency curve, the efficiency of these circular fins is

$$\left.\begin{aligned} W &= (D_{fin} - \text{OD})/2 = (0.10 - 0.05)/2 = 0.025 \text{ m} \\ X_e/X_b &= 0.10/0.05 = 2.0 \\ W\sqrt{\frac{h}{k(\delta/2)}} &= 0.025\sqrt{\frac{40 \text{ W/(m}^2\cdot\text{K)}}{[186 \text{ W(m·K)}](0.0005 \text{ m})}} = 0.52 \end{aligned}\right\} \phi = 0.89$$

The fin area for L = 1 m is

$$A_s = 250 \times 2\pi(D_{fin}^2 - \text{OD}^2)/4 = 2.945 \text{ m}^2$$

The unfinned area for L = 1 m is

$$A_p = \pi \times \text{OD} \times L(1 - N'\delta) = \pi(0.05 \text{ m})(1 \text{ m})(1 - 250 \times 0.001) = 0.118 \text{ m}^2$$

and the total area $A = A_s + A_p = 3.063$ m². Surface efficiency is

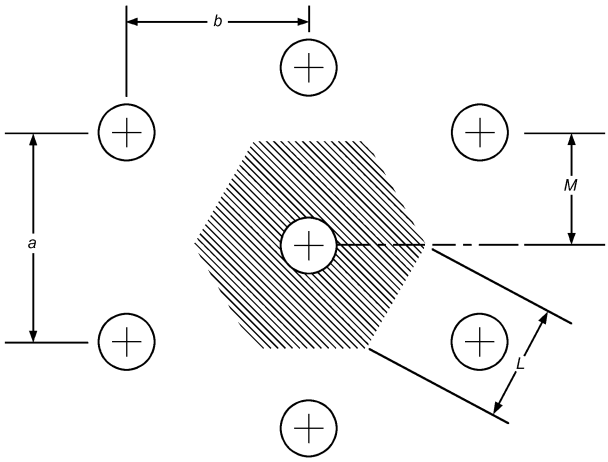

Fig. 10 Hexagonal Tube Array

Licensed for single user. © 2021 ASHRAE, Inc.

$$\phi_s = \frac{\phi A_f + A_s}{A} = 0.894$$

and resistance of the finned surface is

$$R_s = \frac{1}{\phi_s h A} = 9.13 \times 10^{-3} \text{ K/W}$$

Tube wall resistance is

$$R_{wall} = \frac{\ln(\text{OD}/\text{ID})}{2\pi L k_{tube}} = \frac{\ln(5/4.5)}{2\pi(1 \text{ m})[186 \text{ W/(m·K)}]}$$

$$= 9.02 \times 10^{-5} \text{K/W}$$

The rate of heat transfer is then

$$q = \frac{t_i - t_\infty}{R_s + R_{wall}} = 18\,981 \text{ W}$$

Had Schmidt's approach been used for fin efficiency,

$$m = \sqrt{2h/k\delta} = 20.74 \text{ m}^{-1} \quad r_b = \text{OD}/2 = 0.025 \text{ m}$$
$$Z = [(D_{fin}/\text{OD}) - 1][1 + 0.35 \ln(D_{fin}/\text{OD})] = 1.243$$

$$\phi = \frac{\tanh(m r_b Z)}{m r_b Z} = 0.88$$

the same ϕ as given by Figure 5.

Contact Resistance. Fins can be extruded from the prime surface (e.g., short fins on tubes in flooded evaporators or water-cooled condensers) or can be fabricated separately, sometimes of a different material, and bonded to the prime surface. Metallurgical bonds are achieved by furnace-brazing, dip-brazing, or soldering; nonmetallic bonding materials, such as epoxy resin, are also used. Mechanical bonds are obtained by tension-winding fins around tubes (spiral fins) or expanding the tubes into the fins (plate fins). Metallurgical bonding, properly done, leaves negligible thermal resistance at the joint but is not always economical. Contact resistance of a mechanical bond may or may not be negligible, depending on the application, quality of manufacture, materials, and temperatures involved. Tests of plate-fin coils with expanded tubes indicate that substantial losses in performance can occur with fins that have cracked collars, but negligible contact resistance was found in coils with continuous collars and properly expanded tubes (Dart 1959).

Contact resistance at an interface between two solids is largely a function of the surface properties and characteristics of the solids, contact pressure, and fluid in the interface, if any. Eckels (1977) modeled the influence of fin density, fin thickness, and tube diameter on contact pressure and compared it to data for wet and dry coils. Shlykov (1964) showed that the range of attainable contact resistances is large. Sonokama (1964) presented data on the effects of contact pressure, surface roughness, hardness, void material, and the pressure of the gas in the voids. Lewis and Sauer (1965) showed the resistance of adhesive bonds, and Clausing (1964) and Kaspareck (1964) gave data on the contact resistance in a vacuum environment.

Transient Conduction

Often, heat transfer and temperature distribution under transient (i.e., varying with time) conditions must be known. Examples are (1) cold-storage temperature variations on starting or stopping a refrigeration unit, (2) variation of external air temperature and solar irradiation affecting the heat load of a cold-storage room or wall temperatures, (3) time required to freeze a given material under certain conditions in a storage room, (4) quick-freezing objects by direct immersion in brines, and (5) sudden heating or cooling of fluids and solids from one temperature to another.

Lumped Mass Analysis. Often, the temperature within a mass of material can be assumed to vary with time but be uniform within the mass. Examples include a well-stirred fluid in a thin-walled container, or a thin metal plate with high thermal conductivity. In both cases, if the mass is heated or cooled at its surface, the temperature can be assumed to be a function of time only and not location within the body. Such an approximation is valid if

$$\text{Bi} = \frac{h(V/A_s)}{k} \le 0.1$$

where

Bi = Biot number
h = surface heat transfer coefficient
V = material's volume
A_s = surface area exposed to convective and/or radiative heat transfer
k = material's thermal conductivity

The temperature is given by

$$Mc_p \frac{dt}{d\tau} = q_{net} + q_{gen} \tag{12}$$

where

M = body mass
c_p = specific heat
q_{gen} = internal heat generation
q_{net} = net heat transfer rate to substance (into substance is positive, and out of substance is negative)

Equation (12) applies to liquids and solids. If the material is a gas being heated or cooled at constant volume, replace c_p with the constant-volume specific heat c_v. The term q_{net} may include heat transfer by conduction, convection, or radiation and is the difference between the heat transfer rates into and out of the body. The term q_{gen} may include a chemical reaction (e.g., curing concrete) or heat generation from a current passing through a metal.

For a lumped mass M initially at a uniform temperature t_0 that is suddenly exposed to an environment at a different temperature t_∞, the time taken for the temperature of the mass to change to t_f is given by the solution of Equation (12) with $q_{gen} = 0$ as

$$\ln \frac{t_f - t_\infty}{t_0 - t_\infty} = -\frac{hA_s\tau}{Mc_p} \tag{13}$$

where

M = mass of solid
c_p = specific heat of solid
A_s = surface area of solid
h = surface heat transfer coefficient
τ = time required for temperature change
t_f = final solid temperature
t_0 = initial uniform solid temperature
t_∞ = surrounding fluid temperature

Example 4. A copper sphere with diameter d = 1 mm is to be used as a sensing element for a thermostat. It is initially at a uniform temperature of t_0 = 21°C. It is then exposed to the surrounding air at t_∞ = 20°C. The combined heat transfer coefficient is h = 60 W/(m²·K). Determine the time taken for the temperature of the sensing element to reach t_f = 20.5°C. The properties of copper are

$$\rho = 8933 \text{ kg/m}^3 \quad c_p = 385 \text{ J/(kg·K)} \quad k = 401 \text{ W/(m·K)}$$

Solution: Bi = $h(d/2)/k$ = 60.35(0.001/2)/401 = 7.5 × 10⁻⁵, which is much less than 1. Therefore, lumped analysis is valid.

$$M = \rho[4\pi(d/2)^3/3] = 4.677 \times 10^{-6} \text{ kg}$$
$$A_s = \pi d^2 = 3.142 \times 10^{-6} \text{ m}^2$$

Using Equation (13), τ = 6.6 s.

Nonlumped Analysis. When the Biot number is greater than 0.1, variation of temperature with location within the mass is significant.

Licensed for single user. © 2021 ASHRAE, Inc.

One example is the cooling time of meats in a refrigerated space: the meat's size and conductivity do not allow it to be treated as a lumped mass that cools uniformly. Nonlumped problems require solving multidimensional partial differential equations. Many common cases have been solved and presented in graphical forms (Jakob 1949, 1957; Myers 1971; Schneider 1964). In other cases, numerical methods (Croft and Lilley 1977; Patankar 1980) must be used.

Estimating Cooling Times for One-Dimensional Geometries. When a slab of thickness $2L$ or a solid cylinder or solid sphere with outer radius r_m is initially at a uniform temperature t_1, and its surface is suddenly heated or cooled by convection with a fluid at t_∞, a mathematical solution is available for the temperature t as a function of location and time τ. The solution is an infinite series. However, after a short time, the temperature is very well approximated by the first term of the series. The single-term approximations for the three cases are of the form

$$Y = Y_0 f(\mu_1 n) \tag{14}$$

where

$$Y = \frac{t - t_\infty}{t_1 - t_\infty}$$

$$Y_0 = \frac{t_0 - t_\infty}{t_1 - t_\infty} = c_1 \exp(-\mu_1^2 \mathrm{Fo})$$

t_0 = temperature at center of slab, cylinder, or sphere
Fo = $\alpha\tau/L_c^2$ = Fourier number
α = thermal diffusivity of solid = $k/\rho c_p$
L_c = L for slab, r_o for cylinder, sphere
n = x/L for slab, r/r_m for cylinder
c_1, μ_1 = coefficients that are functions of Bi
Bi = Biot number = hL_c/k
$f(\mu_1 n)$ = function of $\mu_1 n$, different for each geometry
x = distance from midplane of slab of thickness $2L$ cooled on both sides
ρ = density of solid
c_p = constant pressure specific heat of solid
k = thermal conductivity of solid

The single term solution is valid for Fo > 0.2. Values of c_1 and μ_1 are given in Table 4 for a few values of Bi, and Couvillion (2004) provides a procedure for calculating them. Expressions for c_1 for each case, along with the function $f(\mu_1 n)$, are as follows:

Slab

$$f(\mu_1 n) = \cos(\mu_1 n) \qquad c_1 = \frac{4\sin(\mu_1)}{2\mu_1 + \sin(2\mu_1)} \tag{15}$$

Long solid cylinder

$$f(\mu_1 n) = J_0(\mu_1 n) \qquad c_1 = \frac{2}{\mu_1} \times \frac{J_1(\mu_1)}{J_0^2(\mu_1) + J_1^2(\mu_1)} \tag{16}$$

Table 4 Values of c_1 and μ_1 in Equations (14) to (17)

	Slab		Solid Cylinder		Solid Sphere	
Bi	c_1	μ_1	c_1	μ_1	c_1	μ_1
0.5	1.0701	0.6533	1.1143	0.9408	1.1441	1.1656
1.0	1.1191	0.8603	1.2071	1.2558	1.2732	1.5708
2.0	1.1785	1.0769	1.3384	1.5995	1.4793	2.0288
4.0	1.2287	1.2646	1.4698	1.9081	1.7202	2.4556
6.0	1.2479	1.3496	1.5253	2.0490	1.8338	2.6537
8.0	1.2570	1.3978	1.5526	2.1286	1.8920	2.7654
10.0	1.2620	1.4289	1.5677	2.1795	1.9249	2.8363
30.0	1.2717	1.5202	1.5973	2.3261	1.9898	3.0372
50.0	1.2727	1.5400	1.6002	2.3572	1.9962	3.0788

where J_0 is the Bessel function of the first kind, order zero. It is available in math tables, spreadsheets, and software packages. $J_0(0) = 1$.

Solid sphere

$$f(\mu_1 n) = \frac{\sin(\mu_1 n)}{\mu_1 n} \qquad c_1 = \frac{4[\sin(\mu_1) - \mu_1 \cos(\mu_1)]}{2\mu_1 - \sin(2\mu_1)} \tag{17}$$

These solutions are presented graphically (McAdams 1954) by Gurnie-Lurie charts (Figures 11 to 13). The charts are also valid for Fo < 0.2.

Example 5. Apples, approximated as 60 mm diameter solid spheres and initially at 30°C, are loaded into a chamber maintained at 0°C. If the surface heat transfer coefficient h = 14 W/(m²·K), estimate the time required for the center temperature to reach t = 1°C.

Properties of apples are

$$\rho = 830 \text{ kg/m}^3 \quad k = 0.42 \text{ W/(m}^2\cdot\text{K)}$$

$$c_p = 3600 \text{ J/(kg·K)} \quad r_m = d/2 = 30 \text{ mm} = 0.03 \text{ m}$$

Solution: Assuming that it will take a long time for the center temperature to reach 1°C, use the one-term approximation Equation (14). From the values given,

$$Y = \frac{t_\infty - t}{t_\infty - t_1} = \frac{0-1}{0-30} = \frac{1}{30}$$

$$n = \frac{r}{r_m} = \frac{0}{0.03} = 0 \qquad \mathrm{Bi} = \frac{hr_m}{k} = \frac{14 \times 0.03}{0.42} = 1$$

$$\alpha = \frac{k}{\rho c_p} = \frac{0.42}{830 \times 3600} = 1.406 \times 10^{-7} \text{ m}^2/\text{s}$$

From Equations (14) and (17) with $\lim(\sin 0/0) = 1$, $Y = Y_0 = c_1 \exp(-\mu^2_1 \mathrm{Fo})$. For Bi = 1, from Table 4, c_1= 1.2732 and μ_1 = 1.5708. Thus,

$$\mathrm{Fo} = -\frac{1}{\mu_1^2}\ln\frac{Y}{c_1} = -\frac{1}{1.5708^2}\ln 0.0333 = 1.476 = \frac{\alpha\tau}{r_m^2} = \frac{0.00545\tau}{(0.1967/2)^2}$$

$$\tau = 2.62 \text{ h}$$

Note that Fo = 0.2 corresponds to an actual time of 1280 s.

Multidimensional Cooling Times. One-dimensional transient temperature solutions can be used to find the temperatures with two- and three-dimensional temperatures of solids. For example, consider a solid cylinder of length $2L$ and radius r_m exposed to a fluid at t_c on all sides with constant surface heat transfer coefficients h_1 on the end surfaces and h_2 on the cylindrical surface, as shown in Figure 14.

The two-dimensional, dimensionless temperature $Y(x_1,r_1,\tau)$ can be expressed as the product of two one-dimensional temperatures $Y_1(x_1,\tau) \times Y_2(r_1,\tau)$, where

Y_1 = dimensionless temperature of constant cross-sectional area slab at (x_1,τ), with surface heat transfer coefficient h_1 associated with two parallel surfaces
Y_2 = dimensionless temperature of solid cylinder at (r_1,τ) with surface heat transfer coefficient h_2 associated with cylindrical surface

From Figures 11 and 12 or Equations (14) to (16), determine Y_1 at $(x_1/L, \alpha\tau/L^2, h_1L/k)$ and Y_2 at $(r_1/r_m, \alpha\tau/r^2_m, h_2r_m/k)$.

Example 6. A 70 mm diameter by 125 mm high soda can, initially at t_1 = 30°C, is cooled in a chamber where the air is at t_∞ = 0°C. The heat transfer coefficient on all surfaces is h = 20 W/(m²·K). Determine the maximum temperature in the can τ = 1 h after starting the cooling. Assume the properties of the soda are those of water, and that the soda inside the can behaves as a solid body.

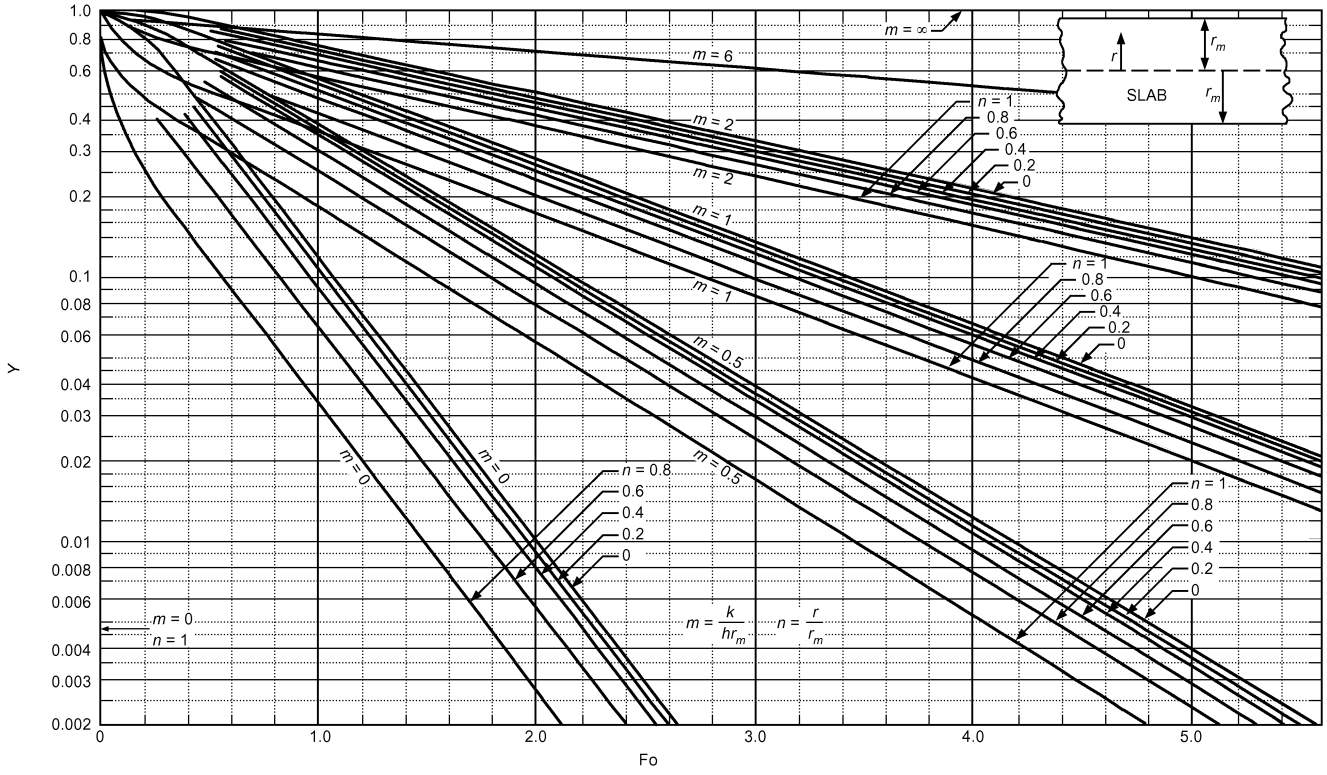

Fig. 11 Transient Temperatures for Infinite Slab, $m = 1/Bi$

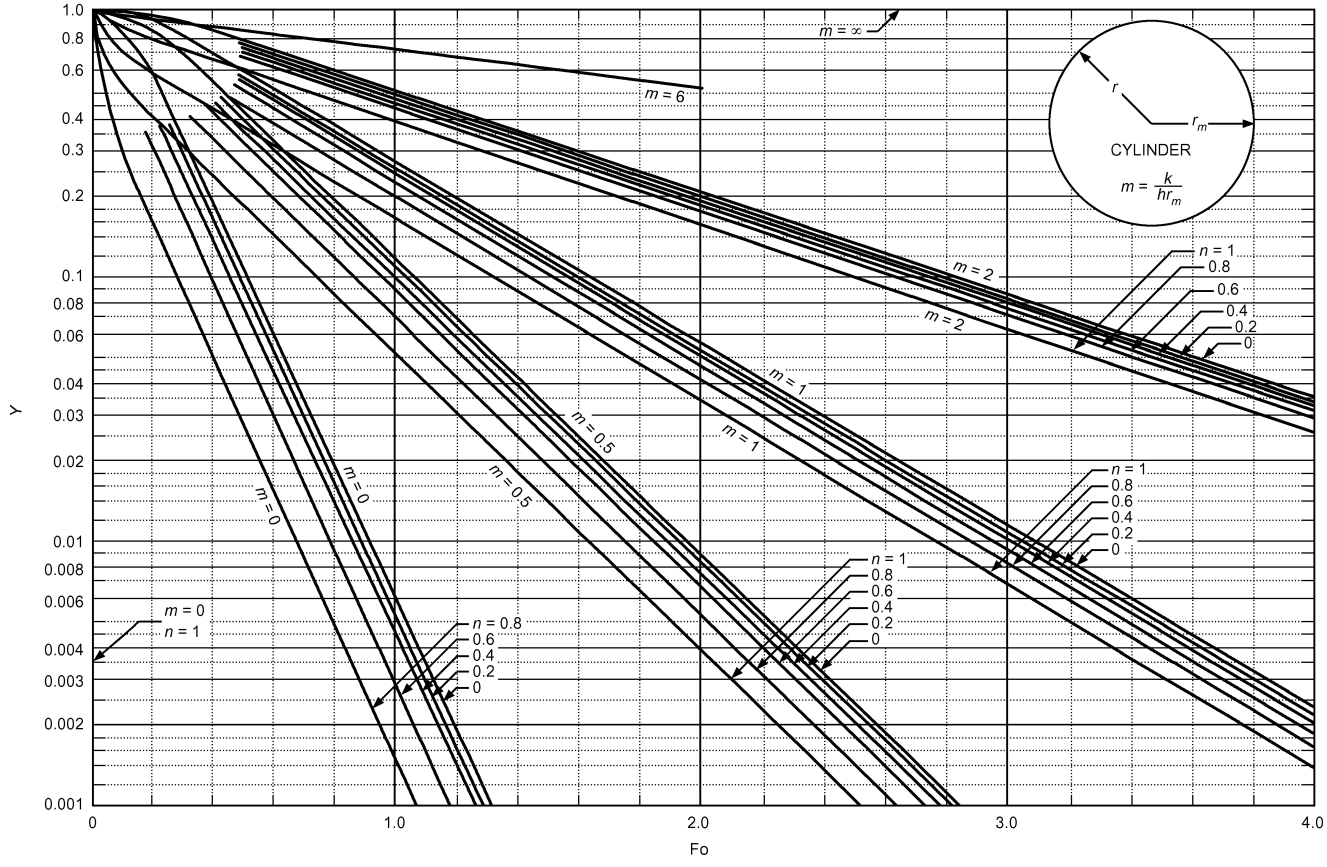

Fig. 12 Transient Temperatures for Infinite Cylinder, $m = 1/Bi$

Licensed for single user. © 2021 ASHRAE, Inc.

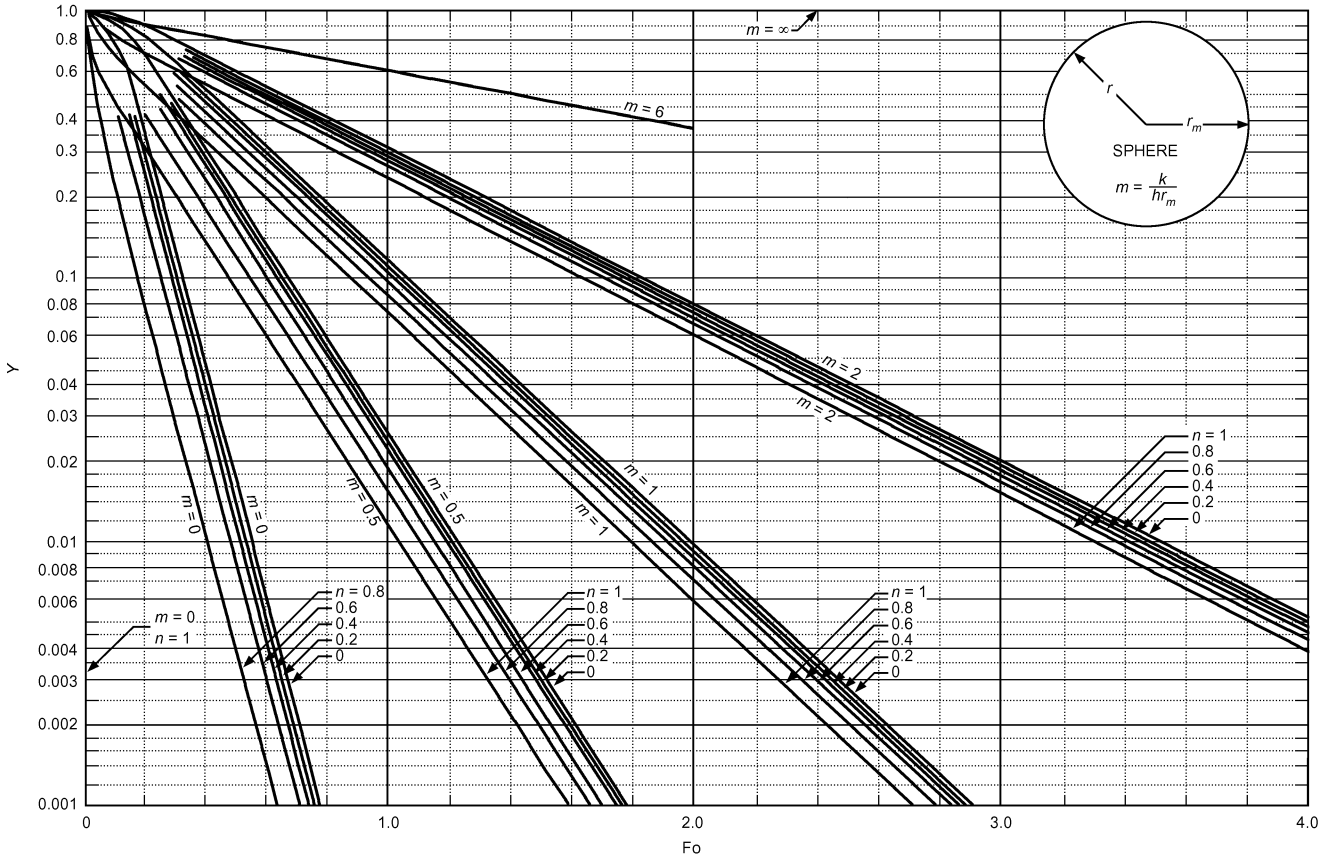

Fig. 13 Transient Temperatures for Sphere, $m = 1/\text{Bi}$

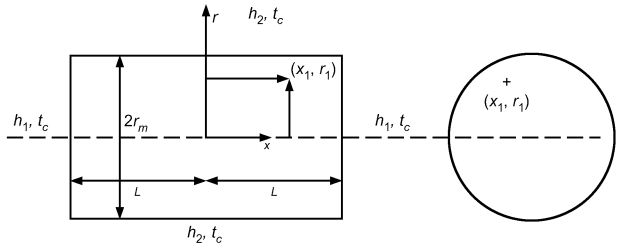

Fig. 14 Solid Cylinder Exposed to Fluid

Solution: Because the cylinder is short, the temperature of the soda is affected by the heat transfer rate from the cylindrical surface and end surfaces. The slowest change in temperature, and therefore the maximum temperature, is at the center of the cylinder. Denoting the dimensionless temperature by Y,

$$Y = Y_{cyl} \times Y_{pl}$$

where Y_{cyl} is the dimensionless temperature of an infinitely long 70 mm diameter cylinder, and Y_{pl} is the dimensionless temperature of a 125 mm thick slab. Each of them is found from the appropriate Biot and Fourier number. For evaluating the properties of water, choose a temperature of 15°C and a pressure of 101.35 kPa. The properties of water are

$\rho = 999.1$ kg/m^3 $k = 0.5894$ W/(m·K) $c_p = 4184$ J/(kg·K)

$\alpha = k/\rho = 1.41 \times 10^{-7}$ m^2/s $\tau = 3600$ s

1. Determine Y_{cyl} at $n = 0$.

$$\text{Bi}_{cyl} = hr_m/k = 20 \times 0.035/0.5894 = 1.188$$

$$\text{Fo}_{cyl} = \alpha\tau/r_m^2 = (1.41 \times 10^{-7}) \times 3600/0.035^2 = 0.4144$$

$\text{Fo}_{cyl} > 0.2$, so use the one-term approximation with Equations (14) and (16).

$$Y_{cyl} = c_1 \exp(-\mu^2_1 \text{Fo}_{cyl}) J_0(0)$$

Interpolating in Table 4 for $\text{Bi}_{cyl} = 1.188$, $\mu_{cyl} = 1.3042$, $J_0(0) = 1$, $c_{cyl} = 1.237$, $Y_{cyl} = 0.572$.

2. Determine Y_{pl} at $n = 0$.

$$\text{Bi}_{pl} = hL/k = 20 \times 0.0625/0.5894 = 2.121$$

$$\text{Fo}_{pl} = 1.41 \times 10^{-7} \times 3600/0.0625^2 = 0.1299$$

$\text{Fo}_{pl} < 0.2$, so the one-term approximation is not valid. Using Figure 11, $Y_{pl} = 0.9705$. Thus,

$$Y = 0.572 \times 0.9705 = 0.5551 = (t - t_\infty)/(t_1 - t_\infty) \Rightarrow t = 16.7°\text{C}$$

Note: The solution may not be exact because convective motion of the soda during heat transfer has been neglected. The example illustrates the use of the technique. For well-stirred soda, with uniform temperature within the can, the lumped mass solution should be used.

3. THERMAL RADIATION

Radiation, unlike conduction and convection, does not need a solid or fluid to transport energy from a high-temperature surface to a lower-temperature one. (Radiation is in fact impeded by such a material.) The rate of radiant energy emission and its characteristics from a surface depend on the underlying material's nature, microscopic arrangement, and absolute temperature. The rate of emission from a surface is independent of the surfaces surrounding it, but the

Licensed for single user. © 2021 ASHRAE, Inc.

rate and characteristics of radiation incident on a surface do depend on the temperatures and spatial relationships of the surrounding surfaces.

Blackbody Radiation

The total energy emitted per unit time per unit area of a black surface is called the **blackbody emissive power** W_b and is given by the **Stefan-Boltzmann law**:

$$W_b = \sigma T^4 \tag{18}$$

where $\sigma = 5.670 \times 10^{-8}$ W/(m^2·K^4) is the Stefan-Boltzmann constant.

Energy is emitted in the form of photons or electromagnetic waves of many different frequencies or wavelengths. Planck showed that the spectral distribution of the energy radiated by a blackbody is

$$W_{b\lambda} = \frac{C_1}{\lambda^5 (e^{C_2/\lambda T} - 1)} \tag{19}$$

where

$W_{b\lambda}$ = blackbody spectral (monochromatic) emissive power, W/m^3
λ = wavelength, m
T = temperature, K
C_1 = first Planck's law constant = 3.742×10^{-16} W·m^2
C_2 = second Planck's law constant = 0.014 388 m·K

The **blackbody spectral emissive power** $W_{b\lambda}$ is the energy emitted per unit time per unit surface area at wavelength λ per unit wavelength band $d\lambda$ around λ; that is, the energy emitted per unit time per unit surface area in the wavelength band $d\lambda$ is equal to $W_{b\lambda} d\lambda$. The Stefan-Boltzmann law can be obtained by integrating Equation (19) over all wavelengths:

$$\int_0^\infty W_{b\lambda}\, d\lambda = \sigma T^4 = W_b$$

Wien showed that the wavelength λ_{max}, at which the monochromatic emissive power is a maximum (not the maximum wavelength), is given by

$$\lambda_{max} T = 2898 \text{ mm·K} \tag{20}$$

Equation (20) is **Wien's displacement** law; the maximum spectral emissive power shifts to shorter wavelengths as temperature increases, such that, at very high temperatures, significant emission eventually occurs over the entire visible spectrum as shorter wavelengths become more prominent. For additional details, see Incropera et al. (2007).

Actual Radiation

The blackbody emissive power W_b and blackbody spectral emissive power $W_{b\lambda}$ are the maxima at a given surface temperature. Actual surfaces emit less and are called **nonblack**. The **emissive power** W of a nonblack surface at temperature T radiating to the hemispherical region above it is given by

$$W = \varepsilon \sigma T^4 \tag{21}$$

where ε is the **total emissivity**. The **spectral emissive power** W_λ of a nonblack surface at a particular wavelength λ is given by

$$W_\lambda = \varepsilon_\lambda W_{b\lambda} \tag{22}$$

where ε_λ is the **spectral emissivity**, and $W_{b\lambda}$ is given by Equation (19). The relationship between ε and ε_λ is given by

$$W = \varepsilon \sigma T^4 = \int_0^\infty W_\lambda d\lambda = \int_0^\infty \varepsilon_\lambda W_{b\lambda} d\lambda$$

or

$$\varepsilon = \frac{1}{\sigma T^4} \int_0^\infty \varepsilon_\lambda W_{b\lambda} d\lambda \tag{23}$$

If ε_λ does not depend on λ, then, from Equation (23), $\varepsilon = \varepsilon_\lambda$, and the surface is called **gray**. Gray surface characteristics are often assumed in calculations. Several classes of surfaces approximate this condition in some regions of the spectrum. The simplicity is desirable, but use care, especially if temperatures are high. The gray assumption is often made because of the absence of information relating ε_λ as a function of λ.

Emissivity is a function of the material, its surface condition, and its surface temperature. Table 5 lists selected values; Modest (2003) and Siegel and Howell (2002) have more extensive lists.

When radiant energy reaches a surface, it is absorbed, reflected, or transmitted through the material. Therefore, from the first law of thermodynamics,

$$\alpha + \rho + \tau = 1$$

where

α = **absorptivity** (fraction of incident radiant energy absorbed)
ρ = **reflectivity** (fraction of incident radiant energy reflected)
τ = **transmissivity** (fraction of incident radiant energy transmitted)

This is also true for spectral values. For an opaque surface, $\tau = 0$ and $\rho + \alpha = 1$. For a black surface, $\alpha = 1$, $\rho = 0$, and $\tau = 0$.

Kirchhoff's law relates emissivity and absorptivity of any opaque surface from thermodynamic considerations; it states that, for any surface where incident radiation is independent of angle or where the surface emits diffusely, $\varepsilon_\lambda = \alpha_\lambda$. If the surface is gray, or the incident radiation is from a black surface at the same temperature, then $\varepsilon = \alpha$ as well, but many surfaces are not gray. For most surfaces listed in Table 5, the total absorptivity for solar radiation is different from the total emissivity for low-temperature radiation, because ε_λ and α_λ vary with wavelength. Much solar radiation is at short wavelengths. Most emissions from surfaces at moderate temperatures are at longer wavelengths.

Platinum black and gold black are almost perfectly black and have absorptivities of about 98% in the infrared region. A small opening in a large cavity approaches blackbody behavior because most of the incident energy entering the cavity is absorbed by repeated reflection within it, and very little escapes the cavity. Thus, the absorptivity and therefore the emissivity of the opening are close to unity. Some flat black paints also exhibit emissivities of 98% over a wide range of conditions. They provide a much more durable surface than gold or platinum black, and are frequently used on radiation instruments and as standard reference in emissivity or reflectance measurements.

Example 7. In outer space, the solar energy flux on a surface is 1150 W/m^2. Two surfaces are being considered for an absorber plate to be used on the surface of a spacecraft: one is black, and the other is specially coated for a solar absorptivity of 0.94 and emissivity of 0.1. Coolant flowing through the tubes attached to the plate maintains the plate at 340 K. The plate surface is normal to the solar flux. For each surface, determine the (1) heat transfer rate to the coolant per unit area of the plate, and (2) temperature of the surface when there is no coolant flow.

Solution: For the black surface,

$$\varepsilon = \alpha = 1, \quad \rho = 0$$

Absorbed energy flux = 1150 W/m^2

Source: Mills (1999).
*Values are for extraterrestrial conditions, except for concrete, snow, and water.

At T_s = 340 K, emitted energy flux = $W_b = 5.67 \times 10^{-8} \times 340^4 = 757.7$ W/m^2.

In space, there is no convection, so an energy balance on the surface gives

$$\text{Heat flux to coolant} = \text{Absorbed energy flux} - \text{Emitted energy flux} = 1150 - 757.7 = 392.3 \text{ W/m}^2$$

For the special surface, use solar absorptivity to determine the absorbed energy flux, and emissivity to calculate the emitted energy flux.

$$\text{Absorbed energy flux} = 0.94 \times 1150 = 1081 \text{ W/m}^2$$
$$\text{Emitted energy flux} = 0.1 \times 757.7 = 75.8 \text{ W/m}^2$$
$$\text{Heat flux to coolant} = 1081 - 75.8 = 1005 \text{ W/m}^2$$

Without coolant flow, heat flux to the coolant is zero. Therefore, absorbed energy flux = emitted energy flux. For the black surface,

$$1150 = 5.67 \times 10^{-8} \times T_s^4 \Rightarrow T_s = 377.1 \text{ K}$$

For the special surface,

$$0.94 \times 1150 = 0.1 \times 5.67 \times 10^{-8} \times T_s^4 \Rightarrow T_s = 660.8 \text{ K}$$

Angle Factor

The foregoing discussion addressed emission from a surface and absorption of radiation leaving surrounding surfaces. Before radiation exchange among a number of surfaces can be addressed, the amount of radiation leaving one surface that is incident on another must be determined.

The fraction of all radiant energy leaving a surface i that is directly incident on surface k is the **angle factor F_{ik}** (also known as **view factor**, **shape factor**, and **configuration factor**). The angle factor from area A_k to area A_j, F_{ki}, is similarly defined, merely by interchanging the roles of i and k. The following relations assume

- All surfaces are gray or black
- Emission and reflection are diffuse (i.e., not a function of direction)
- Properties are uniform over the surfaces
- Absorptivity equals emissivity and is independent of temperature of source of incident radiation
- Material located between radiating surfaces neither emits nor absorbs radiation

These assumptions greatly simplify problems, and give good approximate results in many cases. Some of the relations for the angle factor are as follows.

Reciprocity relation.

$$F_{ik} A_i = F_{ki} A_k \tag{24a}$$

Decomposition relation. For three surfaces i, j, and k, with A_{ij} indicating one surface with two parts denoted by A_i and A_j,

$$A_k F_{k\text{-}ij} = A_k F_{k\text{-}i} + A_k F_{k\text{-}j} \tag{24b}$$

$$A_{ij} F_{ij\text{-}k} = A_i F_{i\text{-}k} + A_j F_{j\text{-}k} \tag{24c}$$

Law of corresponding corners. This law is discussed by Love (1968) and Suryanarayana (1995). Its use is shown in Example 8.

Summation rule. For an enclosure with n surfaces, some of which may be inside the enclosure,

$$\sum_{k=1}^{n} F_{ik} = 1 \tag{24d}$$

Note that a concave surface may "see itself," and $F_{ii} \neq 0$ for such a surface.

Numerical values of the angle factor for common geometries are given in Figure 15. For equations to compute angle factors for many configurations, refer to Siegel and Howell (2002).

Example 8. A picture window, 3 m long and 1.8 m high, is installed in a wall as shown in Figure 16. The bottom edge of the window is on the floor, which is 6 by 10 m. Denoting the window by 1 and the floor by 234, find $F_{234\text{-}1}$.

Solution: From decomposition rule,

$$A_{234} F_{234\text{-}1} = A_2 F_{2\text{-}1} + A_3 F_{3\text{-}1} + A_4 F_{4\text{-}1}$$

By symmetry, $A_2 F_{2\text{-}1} = A_4 F_{4\text{-}1}$ and $A_{234\text{-}1} = A_3 F_{3\text{-}1} + 2A_2 F_{2\text{-}1}$.

$$A_{23} F_{23\text{-}15} = A_2 F_{2\text{-}1} + A_2 F_{2\text{-}5}$$

Licensed for single user. © 2021 ASHRAE, Inc.

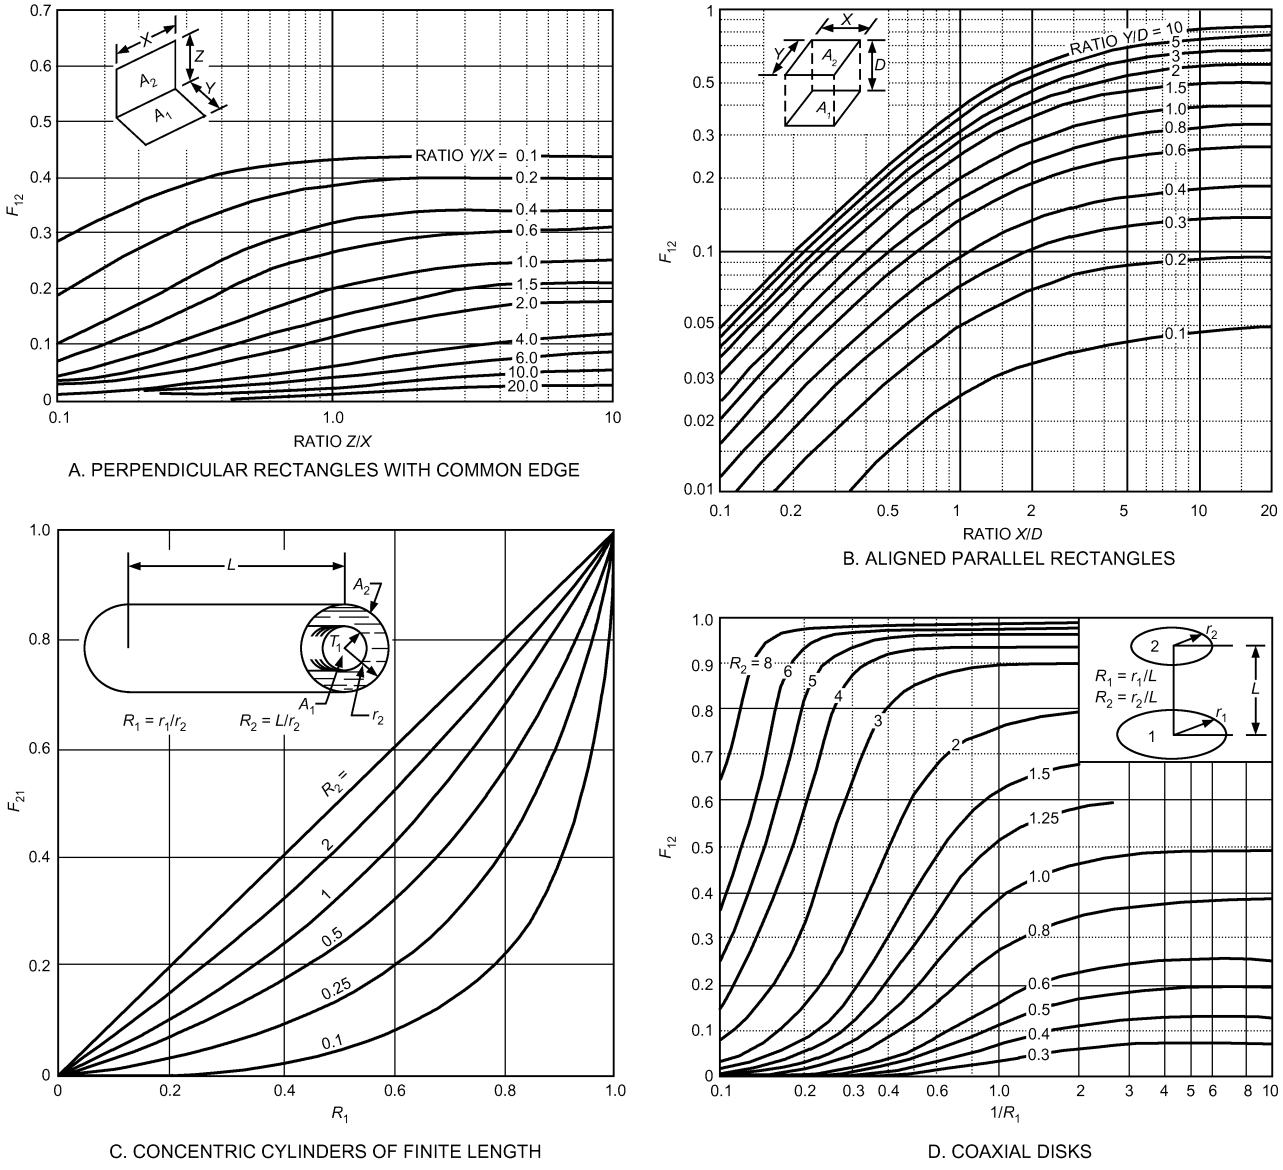

Fig. 15 Radiation Angle Factors for Various Geometries

$$+ A_3F_{3\text{-}1} + A_3F_{3\text{-}5}$$

From the law of corresponding corners, $A_2F_{2\text{-}1} = A_3F_{3\text{-}5}$; therefore $A_{23}F_{23\text{-}5} = A_2F_{2\text{-}5} + A_3F_{3\text{-}1} + 2A_2F_{2\text{-}1}$. Thus,

$$A_{234}F_{234\text{-}1} = A_3F_{3\text{-}1} + A_{23}F_{23\text{-}15} - A_2F_{2\text{-}5} - A_3F_{3\text{-}1} = A_{23}F_{23\text{-}15} - A_2F_{2\text{-}5}$$

$$A_{234} = 60 \text{ m}^2 \qquad A_{23} = 45 \text{ m}^2 \qquad A_2 = 15 \text{ m}^2$$

From Figure 15A with $Y/X = 10/6 = 1.67$ and $Z/X = 1.8/4.5 = 0.4$, $F_{23\text{-}15} = 0.061$. With $Y/X = 10/1.5 = 6.66$ and $Z/X = 1.8/1.5 = 1.2$, $F_{25} = 0.041$. Substituting the values, $F_{234\text{-}1} = 1/60(45 \times 0.061 - 15 \times 0.041) = 0.036$.

Radiant Exchange Between Opaque Surfaces

A surface A_i radiates energy at a rate independent of its surroundings. It absorbs and reflects incident radiation from surrounding surfaces at a rate dependent on its absorptivity. The net heat transfer rate q_i is the difference between the rate radiant energy leaves the surface and the rate of incident radiant energy; it is the rate at which energy must be supplied from an external source to maintain the surface at a constant temperature. The net radiant heat flux from a surface A_i is denoted by q''_i.

Several methods have been developed to solve specific radiant exchange problems. The radiosity method and thermal circuit method are presented here.

Consider the heat transfer rate from a surface of an n-surface enclosure with an intervening medium that does not participate in radiation. All surfaces are assumed gray and opaque. The **radiosity** $\boldsymbol{J_i}$ is the total rate of radiant energy leaving surface i per unit area (i.e., the sum of energy flux emitted and energy flux reflected):

$$J_i = \varepsilon_i W_b + \rho_i G_i \tag{25}$$

where G_i is the total rate of radiant energy incident on surface i per unit area. For opaque gray surfaces, the reflectivity is

$$\rho_i = 1 - \alpha_i = 1 - \varepsilon_i$$

Thus,

$$J_i = \varepsilon_i W_b + (1 - \varepsilon_i) G_i \tag{26}$$

Licensed for single user. © 2021 ASHRAE, Inc.

Note that for a black surface, $\varepsilon = 1$, $\rho = 0$, and $J = W_b$.

The net radiant energy transfer q_i is the difference between the total energy leaving the surface and the total incident energy:

$$q_i = A_i (J_i - G_i) \tag{27}$$

Eliminating G_i between Equations (26) and (27),

$$q_i = \frac{W_{bi} - J_i}{(1 - \varepsilon_i)/\varepsilon_i A_i} \tag{28}$$

Radiosity Method. Consider an enclosure of n isothermal surfaces with areas of $A_1, A_2, \ldots, A_n$, and emissivities of $\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_n$, respectively. Some may be at uniform but different known temperatures, and the remaining surfaces have uniform but different and known heat fluxes. The radiant energy flux incident on a surface G_i is the sum of the radiant energy reaching it from each of the n surfaces:

$$G_i A_i = \sum_{k=1}^{n} F_{ki} J_k A_k = \sum_{k=1}^{n} F_{ik} J_k A_i \quad \text{or} \quad G_i = \sum_{k=1}^{n} F_{ik} J_k \tag{29}$$

Substituting Equation (29) into Equation (26),

$$J_i = \varepsilon_i W_{bi} + (1 - \varepsilon_i) \sum_{k=1}^{n} F_{ik} J_k \tag{30}$$

Combining Equations (30) and (28),

$$J_i = \frac{q_i}{A_i} + \sum_{k=1}^{n} F_{ik} J_k \tag{31}$$

Note that in Equations (30) and (31), the summation includes surface i.

Equation (30) is for surfaces with known temperatures, and Equation (31) for those with known heat fluxes. An opening in the enclosure is treated as a black surface at the temperature of the surroundings. The resulting set of simultaneous, linear equations can be solved for the unknown J_is.

Once the radiosities (J_is) are known, the net radiant energy transfer to or from each surface or the emissive power, whichever is unknown is determined.

For surfaces where E_{bi} is known and q_i is to be determined, use Equation (28) for a nonblack surface. For a black surface, $J_i = W_{bi}$ and Equation (31) can be rearranged to give

$$\frac{q_i}{A_i} = W_{bi} - \sum_{k=1}^{n} F_{ik} J_k \tag{32}$$

At surfaces where q_i is known and E_{bi} is to be determined, rearrange Equation (28):

$$E_{bi} = J_i + q_i \left(\frac{1 - \varepsilon_i}{A_i \varepsilon_i} \right) \tag{33}$$

The temperature of the surface is then

$$T_i = \left(\frac{W_{bi}}{\sigma} \right)^{1/4} \tag{34}$$

A surface in radiant balance is one for which radiant emission is balanced by radiant absorption (i.e., heat is neither removed from nor supplied to the surface). These are called **reradiating**, **insulated**, or **refractory surfaces**. For these surfaces, $q_i = 0$ in Equation (31). After solving for the radiosities, W_{bi} can be found by noting that $q_i = 0$ in Equation (33) gives $W_{bi} = J_i$.

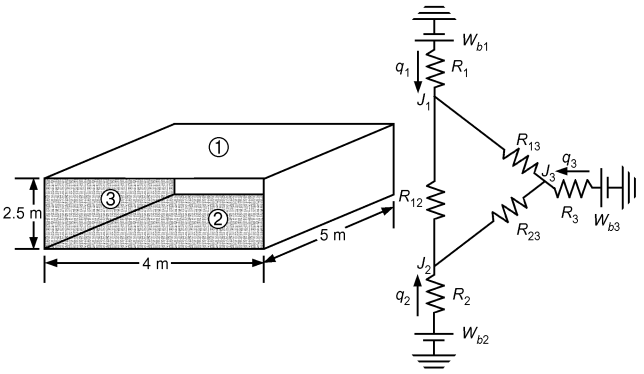

Fig. 17 Diagrams for Example 9

Thermal Circuit Method. Another method to determine the heat transfer rate is using thermal circuits for radiative heat transfer rates. Heat transfer rates from surface i to surface k and surface k to surface i, respectively, are given by

$$q_{i\text{-}k} = A_i F_{i\text{-}k} (J_i - J_k) \quad \text{and} \quad q_{k\text{-}i} = A_k F_{ik\text{-}i} (J_k - J_i)$$

Using the reciprocity relation $A_i F_{i\text{-}k} = A_k F_{k\text{-}i}$, the net heat transfer rate from surface i to surface k is

$$q_{ik} = q_{i\text{-}k} - q_{k\text{-}i} = A_i F_{i\text{-}k} (J_i - J_k) = \frac{J_i - J_k}{1/A_i F_{i\text{-}k}} \tag{35}$$

Equations (28) and (35) are analogous to the current in a resistance, with the numerators representing a potential difference and the denominator representing a thermal resistance. This analogy can be used to solve radiative heat transfer rates among surfaces, as illustrated in Example 9.

Using angle factors and radiation properties as defined assumes that the surfaces are diffuse radiators, which is a good assumption for most nonmetals in the infrared region, but poor for highly polished metals. Subdividing the surfaces and considering the variation of radiation properties with angle of incidence improves the approximation but increases the work required for a solution. Also note that radiation properties, such as absorptivity, have significant uncertainties, for which the final solutions should account.

Example 9. Consider a 4 m wide, 5 m long, 2.5 m high room as shown in Figure 17. Heating pipes, embedded in the ceiling (1), keep its temperature at 40°C. The floor (2) is at 30°C, and the four side walls (3) are at 18°C. The emissivity of each surface is 0.8. Determine the net radiative heat transfer rate to/from each surface.

Solution: Consider the room as a three-surface enclosure. The corresponding thermal circuit is also shown. The heat transfer rates are found after finding the radiosity of each surface by solving the thermal circuit.

From Figure 15A,

$$F_{1\text{-}2} = F_{2\text{-}1} = 0.376$$

From the summation rule, $F_{1\text{-}1} + F_{1\text{-}2} + F_{1\text{-}3} = 1$. With $F_{1\text{-}1} = 0$,

$$F_{1\text{-}3} = 1 - F_{1\text{-}2} = 0.624 = F_{2\text{-}3}$$

$$R_1 = \frac{1 - \varepsilon_1}{A_1 \varepsilon_1} = \frac{1 - 0.8}{20 \times 0.8} = 0.0125 \text{ m}^{-2} = R_2$$

$$R_3 = \frac{1 - \varepsilon_3}{A_3 \varepsilon_3} = \frac{1 - 0.8}{45 \times 0.8} = 0.005\,556 \text{ m}^{-2}$$

Licensed for single user. © 2021 ASHRAE, Inc.

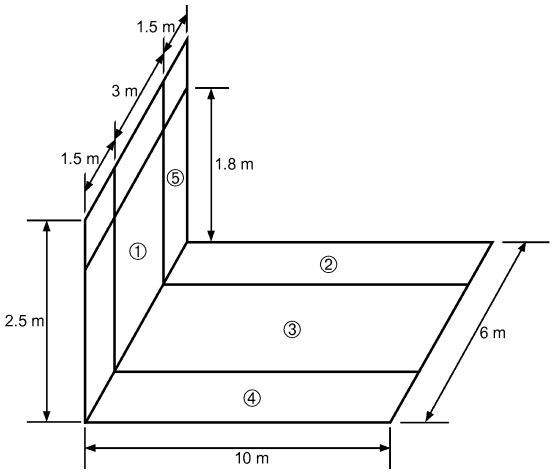

Fig. 16 Diagram for Example 8

$$R_{12} = \frac{1}{A_1 F_{1\text{-}2}} = \frac{1}{20 \times 0.376} = 0.133 \text{ m}^{-2}$$

$$R_{13} = \frac{1}{A_1 F_{1\text{-}3}} = \frac{1}{20 \times 0.624} = 0.080\ 13 \text{ m}^{-2} = R_{23}$$

Performing a balance on each of the three J_i nodes gives

$$\text{Surface 1:} \quad \frac{W_{b1} - J_1}{R_1} + \frac{J_2 - J_1}{R_{12}} + \frac{J_3 - J_1}{R_{13}} = 0$$

$$\text{Surface 2:} \quad \frac{W_{b2} - J_2}{R_2} + \frac{J_1 - J_2}{R_{12}} + \frac{J_3 - J_2}{R_{23}} = 0$$

$$\text{Surface 3:} \quad \frac{W_{b3} - J_3}{R_3} + \frac{J_1 - J_3}{R_{13}} + \frac{J_2 - J_3}{R_{23}} = 0$$

$$W_{b1} = 5.67 \times 10^{-8} \times 313.2^4 = 545.6 \text{ W/m}^2$$

$$W_{b2} = 479.2 \text{ W/m}^2 \qquad W_{b3} = 407.7 \text{ W/m}^2$$

Substituting the values and solving for J_1, J_2, and J_3,

$$J_1 = 524.5 \text{ W/m}^2 \quad J_2 = 475.1 \text{ W/m}^2 \quad J_3 = 418.9 \text{ W/m}^2$$

$$q_1 = \frac{W_{b1} - J_1}{R_1} = \frac{545.6 - 524.5}{0.0125} = 1688 \text{ W}$$

$$q_2 = 328 \text{ W} \qquad q_3 = -2016 \text{ W}$$

Note that floor and ceiling must both be heated because of heat loss from the walls.

Radiation in Gases

Monatomic and diatomic gases such as oxygen, nitrogen, hydrogen, and helium are essentially transparent to thermal radiation. Their absorption and emission bands are confined mainly to the ultraviolet region of the spectrum. The gaseous vapors of most compounds, however, have absorption bands in the infrared region. Carbon monoxide, carbon dioxide, water vapor, sulfur dioxide, ammonia, acid vapors, and organic vapors absorb and emit significant amounts of energy.

Radiation exchange by opaque solids may be considered a surface phenomenon unless the material is transparent or translucent, though radiant energy does penetrate into the material. However, the penetration depths are small. Penetration into gases is very significant.

Table 6 Emissivity of CO_2 and Water Vapor in Air at 24°C

Path Length, m	CO_2, % by Volume		Relative Humidity, %			
	0.1	0.3	1.0	10	50	100
3	0.03	0.06	0.09	0.06	0.17	0.22
30	0.09	0.12	0.16	0.22	0.39	0.47
300	0.16	0.19	0.23	0.47	0.64	0.70

Table 7 Emissivity of Moist Air and CO_2 in Typical Room

Relative Humidity, %	ε_g
10	0.10
50	0.19
75	0.22

Beer's law states that the attenuation of radiant energy in a gas is a function of the product $p_g L$ of the partial pressure of the gas and the path length. The monochromatic absorptivity of a body of gas of thickness L is then

$$\alpha_{\lambda L} = 1 - e^{-\alpha_\lambda L} \tag{36}$$

Because absorption occurs in discrete wavelength bands, the absorptivities of all the absorption bands must be summed over the spectral region corresponding to the temperature of the blackbody radiation passing through the gas. The monochromatic absorption coefficient α_λ is also a function of temperature and pressure of the gas; therefore, detailed treatment of gas radiation is quite complex.

Estimated emissivity for carbon dioxide and water vapor in air at 24°C is a function of concentration and path length (Table 6). Values are for an isothermal hemispherically shaped body of gas radiating at its surface. Among others, Hottel and Sarofim (1967), Modest (2003), and Siegel and Howell (2002) describe geometrical calculations in their texts on radiation heat transfer. Generally, at low values of $p_g L$, the mean path length L (or equivalent hemispherical radius for a gas body radiating to its surrounding surfaces) is four times the mean hydraulic radius of the enclosure. A room with a dimensional ratio of 1:1:4 has a mean path length of 0.89 times the shortest dimension when considering radiation to all walls. For a room with a dimensional ratio of 1:2:6, the mean path length for the gas radiating to all surfaces is 1.2 times the shortest dimension. The mean path length for radiation to the 2 by 6 face is 1.18 times the shortest dimension. These values are for cases where the partial pressure of the gas times the mean path length approaches zero ($p_g L \approx 0$). The factor decreases with increasing values of $p_g L$. For average rooms with approximately 2.4 m ceilings and relative humidity ranging from 10 to 75% at 24°C, the effective path length for carbon dioxide radiation is about 85% of the ceiling height, or 2 m. The effective path length for water vapor is about 93% of the ceiling height, or 2.3 m. The effective emissivity of the water vapor and carbon dioxide radiating to the walls, ceiling, and floor of a room 4.9 by 14.6 m with 2.4 m ceilings is in Table 7.

Radiation heat transfer from the gas to the walls is then

$$q = \sigma A_w \varepsilon_g (T_g^4 - T_w^4) \tag{37}$$

The preceding discussion indicates the importance of gas radiation in environmental heat transfer problems. In large furnaces, gas radiation is the dominant mode of heat transfer, and many additional factors must be considered. Increased pressure broadens the spectral bands, and interaction of different radiating species prohibits simple summation of emissivity factors for the individual species. Nonblackbody conditions require separate calculations of emissivity and absorptivity. Hottel and Sarofim (1967) and McAdams (1954) discuss gas radiation more fully.

4. THERMAL CONVECTION

Convective heat transfer coefficients introduced previously can be estimated using correlations presented in this section.

Forced Convection

Forced-air coolers and heaters, forced-air- or water-cooled condensers and evaporators, and liquid suction heat exchangers are examples of equipment that transfer heat primarily by forced convection. Although some generalized heat transfer coefficient correlations have been mathematically derived from fundamentals, they are usually obtained from correlations of experimental data. Most correlations for forced convection are of the form

$$\mathrm{Nu} = \frac{hL_c}{k} = f(\mathrm{Re}_{Lc}, \mathrm{Pr})$$

where

Nu = Nusselt number
h = convection heat transfer coefficient
L_c = characteristic length
Re_{Lc} = $\rho V L_c/\mu = V L_c/\nu$
V = fluid velocity
Pr = Prandtl number = $c_p \mu/k$
c_p = fluid specific heat
μ = fluid dynamic viscosity
ρ = fluid density
ν = kinematic viscosity = μ/ρ
k = fluid conductivity

Fluid velocity and characteristic length depend on the geometry.

External Flow. When fluid flows over a flat plate, a **boundary layer** forms adjacent to the plate. The velocity of fluid at the plate surface is zero and increases to its maximum free-stream value at the edge of the boundary layer (Figure 18). Boundary layer formation is important because the temperature change from plate to fluid occurs across this layer. Where the boundary layer is thick, thermal resistance is great and the heat transfer coefficient is small. Flow within the boundary layer immediately downstream from the leading edge is laminar. As flow proceeds along the plate, the laminar boundary layer increases in thickness to a critical value. Then, turbulent eddies develop in the boundary layer, except in a thin laminar sublayer adjacent to the plate.

The boundary layer beyond this point is turbulent. The region between the breakdown of the laminar boundary layer and establishment of the turbulent boundary layer is the **transition region**. Because turbulent eddies greatly enhance heat transport into the main stream, the heat transfer coefficient begins to increase rapidly through the transition region. For a flat plate with a smooth leading edge, the turbulent boundary layer starts at distance x_c from the leading edge where the Reynolds number $\mathrm{Re} = V x_c/\nu$ is in the range 300 000 to 500 000 (in some cases, higher). In a plate with a blunt front edge or other irregularities, it can start at much smaller Reynolds numbers.

Internal Flow. For tubes, channels, or ducts of small diameter at sufficiently low velocity, the laminar boundary layers on each wall grow until they meet. This happens when the Reynolds number based on tube diameter, $\mathrm{Re} = V_{avg} D/\nu$, is less than 2000 to 2300. Beyond this point, the velocity distribution does not change, and no transition to turbulent flow occurs. This is called **fully developed laminar flow**. When the Reynolds number is greater than 10 000, the boundary layers become turbulent before they meet, and fully developed turbulent flow is established (Figure 19). If flow is turbulent, three different flow regions exist. Immediately next to the wall is a **laminar sublayer**, where heat transfer occurs by thermal conduction; next is a transition region called the **buffer layer**, where both eddy mixing and conduction effects are significant; the final layer, extending to the pipe's axis, is the **turbulent region**, where the dominant mechanism of transfer is eddy mixing.

In most equipment, flow is turbulent. For low-velocity flow in small tubes, or highly viscous liquids such as glycol, the flow may be laminar.

The characteristic length for internal flow in pipes and tubes is the inside diameter. For noncircular tubes or ducts, the **hydraulic diameter D_h** is used to compute the Reynolds and Nusselt numbers. It is defined as

$$D_h = 4 \times \frac{\text{Cross-sectional area for flow}}{\text{Total wetted perimeter}} \tag{38}$$

Inserting expressions for cross-sectional area and wetted perimeter of common cross sections shows that the hydraulic diameter is equal to

- The diameter of a round pipe
- Twice the gap between two parallel plates
- The difference in diameters for an annulus
- The length of the side for square tubes or ducts

Table 8 lists various forced-convection correlations. In general, the Nusselt number is determined by the flow geometry, Reynolds number, and Prandtl number. One often useful form for turbulent internal flow is known as **Colburn's analogy**:

$$j = \frac{\mathrm{Nu}}{\mathrm{RePr}^{1/3}} = \frac{f_F}{2}$$

where f_F is the Fanning friction factor (1/4 of the Darcy-Weisbach friction factor in Chapter 3) and j is the Colburn j-factor. It is related to the friction factor by the interrelationship of the transport of momentum and energy in turbulent flow. These factors are plotted in Figure 20.

Table 8 Forced-Convection Correlations

I. General Correlation $\mathrm{Nu} = f(\mathrm{Re}, \mathrm{Pr})$

II. Internal Flows for Pipes and Ducts: Characteristic length = D, pipe diameter, or D_h, hydraulic diameter.

$$\mathrm{Re} = \frac{\rho V_{avg} D_h}{\mu} = \frac{m D_h}{A_c \mu} = \frac{Q D_h}{A_c \nu} = \frac{4\dot{m}}{\mu P_{wet}} = \frac{4Q}{\nu P_{wet}}$$

where m = mass flow rate, Q = volume flow rate, P_{wet} = wetted perimeter, A_c = cross-sectional area, and ν = kinematic viscosity (μ/ρ).

$$\frac{\mathrm{Nu}}{\mathrm{Re}\,\mathrm{Pr}^{1/3}} = \frac{f}{2}$$ Colburn's analogy (turbulent) (T8.1)

Laminar: Re < 2300

$$\mathrm{Nu} = 1.86\left(\frac{\mathrm{Re}\,\mathrm{Pr}}{L/D}\right)^{1/3}\left(\frac{\mu}{\mu_s}\right)^{0.14} \qquad \frac{L}{D} < \frac{\mathrm{Re}\,\mathrm{Pr}}{8}\left(\frac{\mu}{\mu_s}\right)^{0.42}$$ (T8.2)[a]

Developing

$$\mathrm{Nu} = 3.66 + \frac{0.065(D/L)\mathrm{Re}\,\mathrm{Pr}}{1 + 0.04[(D/L)\mathrm{Re}\,\mathrm{Pr}]^{2/3}}$$ (T8.3)

Fully developed, round

$\mathrm{Nu} = 3.66$ Uniform surface temperature (T8.4a)

$\mathrm{Nu} = 4.36$ Uniform heat flux (T8.4b)

Turbulent:

$\mathrm{Nu} = 0.023\,\mathrm{Re}^{4/5}\,\mathrm{Pr}^{0.4}$ Heating fluid, $\mathrm{Re} \geq 10\,000$ (T8.5a)[b]

Fully developed

$\mathrm{Nu} = 0.023\,\mathrm{Re}^{4/5}\,\mathrm{Pr}^{0.3}$ Cooling fluid, $\mathrm{Re} \geq 10\,000$ (T8.5b)[b]

Evaluate properties at bulk temperature t_b except μ_s and t_s at surface temperature

$$\mathrm{Nu} = \frac{(f_s/2)(\mathrm{Re} - 1000)\mathrm{Pr}}{1 + 12.7(f_s/2)^{1/2}(\mathrm{Pr}^{2/3} - 1)}\left[1 + \left(\frac{D}{L}\right)^{2/3}\right] \qquad f_s = \frac{1}{(1.58\ln \mathrm{Re} - 3.28)^2}$$ (T8.6)[c]

For fully developed flows, set $D/L = 0$.

Multiply Nu by $(T/T_s)^{0.45}$ for gases and by $(\mathrm{Pr}/\mathrm{Pr}_s)^{0.11}$ for liquids

$$\mathrm{Nu} = 0.027\,\mathrm{Re}^{4/5}\,\mathrm{Pr}^{1/3}\left(\frac{\mu}{\mu_s}\right)^{0.14}$$ For viscous fluids (T8.7)[a]

For noncircular tubes, use hydraulic mean diameter D_h in the equations for Nu for an approximate value of h.

III. External Flows for Flat Plate: Characteristic length = L = length of plate. $\mathrm{Re} = VL/\nu$.

All properties at arithmetic mean of surface and fluid temperatures.

Laminar boundary layer: $\mathrm{Re} < 5 \times 10^5$

$\mathrm{Nu} = 0.332\,\mathrm{Re}^{1/2}\mathrm{Pr}^{1/3}$ Local value of h (T8.8)

$\mathrm{Nu} = 0.664\,\mathrm{Re}^{1/2}\mathrm{Pr}^{1/3}$ Average value of h (T8.9)

Turbulent boundary layer: $\mathrm{Re} > 5 \times 10^5$

$\mathrm{Nu} = 0.0296\,\mathrm{Re}^{4/5}\mathrm{Pr}^{1/3}$ Local value of h (T8.10)

Turbulent boundary layer beginning at leading edge: All Re

$\mathrm{Nu} = 0.037\,\mathrm{Re}^{4/5}\mathrm{Pr}^{1/3}$ Average value of h (T8.11)

Laminar-turbulent boundary layer: $\mathrm{Re} > 5 \times 10^5$

$\mathrm{Nu} = (0.037\,\mathrm{Re}^{4/5} - 871)\mathrm{Pr}^{1/3}$ Average value $\mathrm{Re}_c = 5 \times 10^5$ (T8.12)

IV. External Flows for Cross Flow over Cylinder: Characteristic length = D = diameter. $\mathrm{Re} = VD/\nu$.

All properties at arithmetic mean of surface and fluid temperatures.

$$\mathrm{Nu} = 0.3 + \frac{0.62\,\mathrm{Re}^{1/2}\mathrm{Pr}^{1/3}}{[1 + (0.4/\mathrm{Pr})^{2/3}]^{1/4}}\left[1 + \left(\frac{\mathrm{Re}}{282\,000}\right)^{5/8}\right]^{4/5}$$ Average value of h (T8.14)[d]

V. Simplified Approximate Equations: h is in W/(m²·K), V is in m/s, D is in m, and t is in °C.

Flows in pipes, $\mathrm{Re} > 10\,000$

Atmospheric air (0 to 200°C): $h = (3.76 - 0.00497t)V^{0.8}/D^{0.2}$ (T8.15a)[e]

Water (3 to 200°C): $h = (1206 + 23.9t)V^{0.8}/D^{0.2}$ (T8.15b)[e]

Water (4 to 104°C): $h = (1431 + 20.9t)V^{0.8}/D^{0.2}$ (McAdams 1954) (T8.15c)[g]

Flow over cylinders

Atmospheric air: 0°C < t < 200°C, where t = arithmetic mean of air and surface temperature.

$h = 2.755V^{0.471}/D^{0.529}$ $35 < \mathrm{Re} < 5000$ (T8.16a)

$h = (4.22 - 0.002\,57t)V^{0.633}/D^{0.367}$ $5000 < \mathrm{Re} < 50\,000$ (T8.16b)

Water: 5°C < t < 90°C, where t = arithmetic mean of water and surface temperature.

$h = (461.8 + 2.01t)V^{0.471}/D^{0.529}$ $35 < \mathrm{Re} < 5000$ (T8.17a)

$h = (1012 + 9.19t)V^{0.633}/D^{0.367}$ $5000 < \mathrm{Re} < 50\,000$ (T8.17b)[f]

VI. External Flow over Spheres: Characteristic length = D = diameter. $\mathrm{Re} = VD/\nu$.

All properties at arithmetic mean of surface and fluid bulk temperature, except μ_s at surface temperature.

$$\overline{\mathrm{Nu}}_D = 2 + (0.4\mathrm{Re}_D^{1/2} + 0.06\,\mathrm{Re}_D^{2/3})\mathrm{Pr}^{0.4}(\mu/\mu_s)^{1/4}$$ (T8.18)

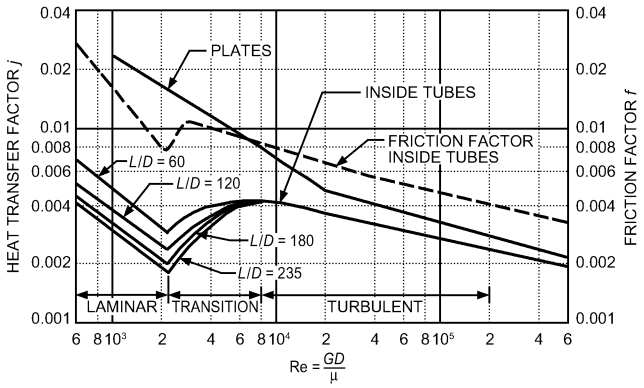

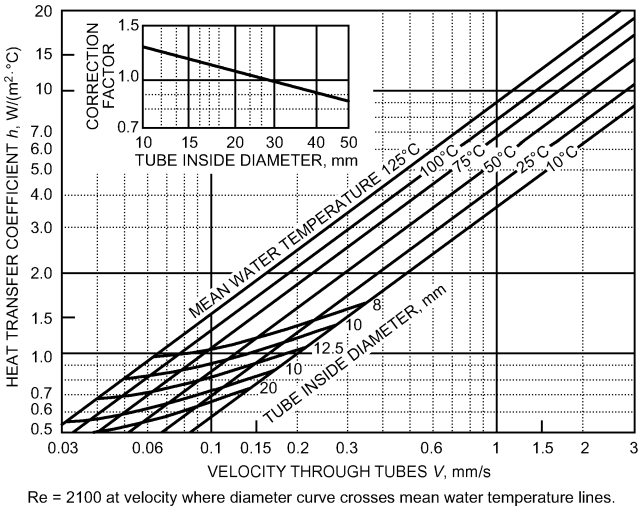

Fig. 20 Typical Dimensionless Representation of Forced-Convection Heat Transfer

Re = 2100 at velocity where diameter curve crosses mean water temperature lines.

Fig. 21 Heat Transfer Coefficient for Turbulent Flow of Water Inside Tubes

Simplified correlations for atmospheric air are also given in Table 8. Figure 21 gives graphical solutions for water.

Example 10. An uninsulated 3 m ID spherical tank with 0.01 m walls is used to store iced water. Winds at V = 25 km/h and T_∞ = 30°C blow over the outside of the tank. What is the rate of heat gain to the iced water? Neglect radiation, conduction resistance of tank wall, and convection resistance between ice water and tank; the outer surface temperature of the tank is 0°C.

Because the geometry is for forced convection over a sphere, use Equation (T8.18). Use the properties of air at 101.325 kPa pressure and the freestream temperature of T_∞ = 30°C: k = 0.0259 W/(m·K), ν = 1.608×0^{-5} m²/s, $\mu = 1.872 \times 10^{-5}$ kg/(m·s), Pr = 0.728, and $\mu_s = 1.729 \times 10^{-5}$ kg/(m·s) at 0°C.

$$\mathrm{Re} = \frac{VD}{\nu} = \frac{[(25 \times 1000/3600)\ \mathrm{m/s}](3.02\ \mathrm{m})}{1.608 \times 10^{-5}\ \mathrm{m^2/s}} = 1.304 \times 10^6$$

$$\mathrm{Nu} = \frac{hD}{k} = 2 + \left[0.4\mathrm{Re}^{0.5} + 0.06\mathrm{Re}^{2/3}\right]\mathrm{Pr}^{0.4}(\mu/\mu_s)^{1/4}$$

$$= 2 + \left[0.4(1.304 \times 10^6)^{0.5} + 0.06(1.304 \times 10^6)^{2/3}\right]$$

$$\times (0.7282)^{0.4}\left(\frac{1.872 \times 10^{-5}}{1.729 \times 10^{-5}}\right)^{1/4} = 1056$$

Note that for gases, the $(\mu/\mu_s)^{1/4}$ property correction is often negligible. For liquids, it is often significant.

$$h = \frac{k}{D}\mathrm{Nu} = \frac{0.02588\ \mathrm{W/(m^2 \cdot K)}}{3.02\ \mathrm{m}}(1056) = 9.05\ \mathrm{W/(m^2 \cdot K)}$$

The rate of heat transfer to the iced water is

$$q = hA_s(T_s - T_\infty) = h(\pi D^2)(T_s - T_\infty) = [9.05\ \mathrm{W/(m^2 \cdot K)}][\pi(3.02\ \mathrm{m})^2](30 - 0)\mathrm{K} = 7780\ \mathrm{W}$$

With a uniform tube surface temperature and heat transfer coefficient, the exit temperature can be calculated using

$$\ln\frac{t_s - t_e}{t_s - t_i} = -\frac{hA}{mc_p} \tag{39}$$

where t_i and t_e are the inlet and exit bulk temperatures of the fluid, t_s is the pipe/duct surface temperature, and A is the surface area inside the pipe/duct. The convective heat transfer coefficient varies in the direction of flow because of the temperature dependence of the fluid properties. In such cases, it is common to use an average value of h in Equation (39) computed either as the average of h evaluated at the inlet and exit fluid temperatures or evaluated at the average of the inlet and exit temperatures.

With uniform surface heat flux q'', the temperature of fluid t at any section can be found by applying the first law of thermodynamics:

$$\dot{m}\, c_p(t - t_i) = q''A \tag{40}$$

The surface temperature can be found using

$$q'' = h(t_s - t) \tag{41}$$

With uniform surface heat flux, surface temperature increases in the direction of flow along with the fluid.

Natural Convection. Heat transfer with fluid motion resulting solely from temperature differences (i.e., from temperature-dependent density and gravity) is natural (free) convection. Natural-convection heat transfer coefficients for gases are generally much lower than those for forced convection, and it is therefore important not to ignore radiation in calculating the total heat loss or gain. Radiant transfer may be of the same order of magnitude as natural convection, even at room temperatures; therefore, both modes must be considered when computing heat transfer rates from people, furniture, and so on in buildings (see Chapter 9).

Natural convection is important in a variety of heating and refrigeration equipment, such as (1) gravity coils used in high-humidity cold-storage rooms and in roof-mounted refrigerant condensers, (2) the evaporator and condenser of household refrigerators, (3) baseboard radiators and convectors for space heating, and (4) cooling panels for air conditioning. Natural convection is also involved in heat loss or gain to equipment casings and interconnecting ducts and pipes.

Consider heat transfer by natural convection between a cold fluid and a hot vertical surface. Fluid in immediate contact with the surface is heated by conduction, becomes lighter, and rises because of

the difference in density of the adjacent fluid. The fluid's viscosity resists this motion. The heat transfer rate is influenced by fluid properties, temperature difference between the surface at t_s and environment at t_∞, and characteristic dimension L_c. Some generalized heat transfer coefficient correlations have been mathematically derived from fundamentals, but they are usually obtained from correlations of experimental data. Most correlations for natural convection are of the form

$$\mathrm{Nu} = \frac{hL_c}{k} = f(\mathrm{Ra}_{Lc}, \mathrm{Pr})$$

where

Nu = Nusselt number
H = convection heat transfer coefficient
L_c = characteristic length
K = fluid thermal conductivity
Ra_{Lc} = Rayleigh number = $g\beta\,\Delta t L_c^3/\nu\alpha$
$\Delta t = |t_s - t_\infty|$
g = gravitational acceleration
β = coefficient of thermal expansion
ν = fluid kinematic viscosity = μ/ρ
α = fluid thermal diffusivity = $k/\rho c_p$
Pr = Prandtl number = ν/α

Correlations for a number of geometries are given in Table 9. Other information on natural convection is available in the Bibliography under Heat Transfer, General.

Comparison of experimental and numerical results with existing correlations for natural convective heat transfer coefficients indicates that caution should be used when applying coefficients for (isolated) vertical plates to vertical surfaces in enclosed spaces (buildings). Altmayer et al. (1983) and Bauman et al. (1983) developed improved correlations for calculating natural convective heat transfer from vertical surfaces in rooms under certain temperature boundary conditions.

Natural convection can affect the heat transfer coefficient in the presence of weak forced convection. As the forced-convection effect (i.e., the Reynolds number) increases, "mixed convection" (superimposed forced-on-free convection) gives way to pure forced convection. In these cases, consult other sources [e.g., Grigull et al. (1982); Metais and Eckert (1964)] describing combined free and forced convection, because the heat transfer coefficient in the mixed-convection region is often larger than that calculated based on the natural- or forced-convection calculation alone. Metais and Eckert (1964) summarize natural-, mixed-, and forced-convection regimes for vertical and horizontal tubes. Figure 22 shows the approximate limits for horizontal tubes. Other studies are described by Grigull et al. (1982).

Example 11. A horizontal electric immersion heater of 10 mm diameter D and 400 mm length L is rated at q = 733 W. Estimate the surface temperature t_s if immersed in 20°C t_∞ water.

Solution: Because the geometry is for natural convection from a horizontal cylinder, use Equation (T9.10). If the allowable surface temperature of the heater were given, and the need were to calculate the maximum allowable power rating, this would be a straightforward sequence of calculations:

1. Calculate the film temperature $t_f = (t_s + t_\infty)/2$
2. Look up the needed water properties k, ν, Pr, α, and β at t_f.
3. Calculate Rayleigh number Ra.
4. Use Equation (T9.10) to calculate Nusselt number Nu.
5. Calculate $h = \mathrm{Nu}\,k/D$.
6. $q = h\pi DL(t_s - t_\infty)$

However, in this case, given q and needing t_s, the solution is iterative. First, guess the solution t_s, execute items 1 to 5 in the preceding sequence, and use the resulting h to calculate $t_s = t_\infty + q/(h\pi DL)$. If necessary, use this value as a new guess for t_s and repeat the process.

Assume t_s = 64°C. Then t_f = (64 + 20)/2 = 42°C = 315 K. Use k = 0.634 W/(m·K), $\nu = 6.25 \times 10^{-7}$ m²/s, $\alpha = 1.53 \times 10^{-7}$ m²/s, Pr = 4.08, and $\beta = 0.4004 \times 10^{-3}$/K.

$$\mathrm{Ra} = \frac{g\beta\Delta TD^3}{\nu\alpha} = 1.804 \times 10^6$$

$$\mathrm{Nu} = \left\{ 0.6 + \frac{0.387\mathrm{Ra}^{1/6}}{\left[1 + (0.559/\mathrm{Pr})^{9/16}\right]^{8/27}} \right\}^2 = 20.5$$

$$h = \mathrm{Nu}\,k/D = 1301\ \mathrm{W/(m^2 \cdot K)}$$

$$t_s = t_\infty + q/(h\pi DL) = 64.8°\mathrm{C}$$

The initial guess was close enough; another iteration is unnecessary.

Example 12. Chilled water at 5°C flows inside a freely suspended horizontal 20 mm OD pipe at a velocity of 2.5 m/s. Surrounding air is at 30°C, 70% rh. The pipe is to be insulated with cellular glass having a thermal conductivity of 0.045 W/(m·K). Determine the radial thickness of the insulation to prevent condensation of water on the outer surface.

Solution: In Figure 23,

t_{fi} = 5°C t_{fo} = 30°C d_o = OD of tube = 0.02 m
k_i = thermal conductivity of insulation material = 0.045 W/(m·K)

From the problem statement, the outer surface temperature t_o of the insulation should not be less than the dew-point temperature of air. The dew-point temperature of air at 30°C, 70% rh = 23.93°C. To determine

Table 9 Natural Convection Correlations

I. General relationships	$\mathrm{Nu} = f(\mathrm{Ra}, \mathrm{Pr})$ or $f(\mathrm{Ra})$		(T9.1)
Characteristic length depends on geometry	$\mathrm{Ra} = \mathrm{Gr}\,\mathrm{Pr} \quad \mathrm{Gr} = \frac{g\beta\rho^2\lvert\Delta t\rvert L^3}{\mu^2} \quad \mathrm{Pr} = \frac{c_p\mu}{k} \quad \Delta t = \lvert t_s - t_\infty\rvert$		
II. Vertical plate			
t_s = constant	$\mathrm{Nu} = 0.68 + \frac{0.67\mathrm{Ra}^{1/4}}{[1 + (0.492/\mathrm{Pr})^{9/16}]^{4/9}}$	$10^{-1} < \mathrm{Ra} < 10^9$	(T9.2)[a]
Characteristic dimension: L = height Properties at $(t_s + t_\infty)/2$ except β at t_∞	$\mathrm{Nu} = \left\{0.825 + \frac{0.387\mathrm{Ra}^{1/6}}{[1 + (0.492/\mathrm{Pr})^{9/16}]^{8/27}}\right\}^2$	$10^9 < \mathrm{Ra} < 10^{12}$	(T9.3)[a]
q''_s = constant Characteristic dimension: L = height Properties at $t_{s,\,L/2} - t_\infty$ except β at t_∞	$\mathrm{Nu} = \left\{0.825 + \frac{0.387\mathrm{Ra}^{1/6}}{[1 + (0.437/\mathrm{Pr})^{9/16}]^{8/27}}\right\}^2$	$10^{-1} < \mathrm{Ra} < 10^{12}$	(T9.4)[a]
Equations (T9.2) and (T9.3) can be used for vertical cylinders if $D/L > 35/\mathrm{Gr}^{1/4}$ where D is diameter and L is axial length of cylinder			
III. Horizontal plate			
Characteristic dimension = $L = A/P$, where A is plate area and P is perimeter Properties of fluid at $(t_s + t_\infty)/2$			
Downward-facing cooled plate and upward-facing heated plate	$\mathrm{Nu} = 0.96\,\mathrm{Ra}^{1/6}$	$1 < \mathrm{Ra} < 200$	(T9.5)[b]
	$\mathrm{Nu} = 0.59\,\mathrm{Ra}^{1/4}$	$200 < \mathrm{Ra} < 10^4$	(T9.6)[b]
	$\mathrm{Nu} = 0.54\,\mathrm{Ra}^{1/4}$	$2.2 \times 10^4 < \mathrm{Ra} < 8 \times 10^6$	(T9.7)[b]
	$\mathrm{Nu} = 0.15\,\mathrm{Ra}^{1/3}$	$8 \times 10^6 < \mathrm{Ra} < 1.5 \times 10^9$	(T9.8)[b]
Downward-facing heated plate and upward-facing cooled plate	$\mathrm{Nu} = 0.27\,\mathrm{Ra}^{1/4}$	$10^5 < \mathrm{Ra} < 10^{10}$	(T9.9)[b]
IV. Horizontal cylinder Characteristic length = d = diameter Properties of fluid at $(t_s + t_\infty)/2$ except β at t_∞	$\mathrm{Nu} = \left\{0.6 + \frac{0.387\ \mathrm{Ra}^{1/6}}{[1 + (0.559/\mathrm{Pr})^{9/16}]^{8/27}}\right\}^2$	$10^{-6} < \mathrm{Ra} < 10^{13}$	(T9.10)[c]
V. Sphere Characteristic length = D = diameter Properties at $(t_s + t_\infty)/2$ except β at t_∞	$\mathrm{Nu} = 2 + \frac{0.589\ \mathrm{Ra}^{1/4}}{[1 + (0.469/\mathrm{Pr})^{9/16}]^{4/9}}$	$\mathrm{Ra} < 10^{11}$	(T9.11)[d]
VI. Horizontal wire Characteristic dimension = D = diameter Properties at $(t_s + t_\infty)/2$	$\frac{2}{\mathrm{Nu}} = \ln\left(1 + \frac{3.3}{c\mathrm{Ra}^n}\right)$	$10^{-8} < \mathrm{Ra} < 10^6$	(T9.12)[e]
VII. Vertical wire Characteristic dimension = D = diameter; L = length of wire Properties at $(t_s + t_\infty)/2$	$\mathrm{Nu} = c\,(\mathrm{Ra}\,D/L)^{0.25} + 0.763c^{(1/6)}(\mathrm{Ra}\,D/L)^{(1/24)}$ In both Equations (T9.12) and (T9.13), $c = \frac{0.671}{[1 + (0.492/\mathrm{Pr})^{(9/16)}]^{(4/9)}}$ and $n = 0.25 + \frac{1}{10 + 5(\mathrm{Ra})^{0.175}}$	$c\,(\mathrm{Ra}\,D/L)^{0.25} > 2 \times 10^{-3}$	(T9.13)[e]
VIII. Simplified equations with air at mean temperature of 21°C: h is in W/(m²·K), L and D are in m, and Δt is in °C.			
Vertical surface	$h = 1.33\left(\frac{\Delta t}{L}\right)^{1/4}$	$10^5 < \mathrm{Ra} < 10^9$	(T9.14)
	$h = 1.26(\Delta t)^{1/3}$	$\mathrm{Ra} > 10^9$	(T9.15)
Horizontal cylinder	$h = 1.04\left(\frac{\Delta T}{D}\right)^{1/4}$	$10^5 < \mathrm{Ra} < 10^9$	(T9.16)
	$h = 1.23(\Delta t)^{1/3}$	$\mathrm{Ra} > 10^9$	(T9.17)

Sources: [a]Churchill and Chu (1975a), [b]Lloyd and Moran (1974), Goldstein et al. (1973), [c]Churchill and Chu (1975b), [d]Churchill (1990), [e]Fujii et al. (1986).

the outer diameter of the insulation, equate the heat transfer rate per unit length of pipe (from the outer surface of the pipe to the water) to the heat transfer rate per unit length from the air to the outer surface:

$$\frac{t_o - t_{fi}}{\frac{1}{h_i d_i} + \frac{1}{2k_i}\ln\frac{d_o}{d_i}} = \frac{t_{fo} - t_o}{\frac{1}{h_{ot} d_o}} \tag{42}$$

Heat transfer from the outer surface is by natural convection to air, so the surface heat transfer coefficient h_{ot} is the sum of the convective heat transfer coefficient h_o and the radiative heat transfer coefficient h_r. With an assumed emissivity of 0.7 and using Equation (4), h_r = 4.3 W/(m²·K). To determine the value of d_o, the values of the heat transfer coefficients associated with the inner and outer surfaces (h_i and h_o, respectively) are needed. Compute the value of h_i using Equation (T8.5a). Properties of water at an assumed temperature of 5°C are

Licensed for single user. © 2021 ASHRAE, Inc.

$\rho_w = 1000$ kg/m^3 $\mu_w = 0.001\,518$ (N·s)/m^2 $c_{pw} = 4197$ W/(m·K)

$k_w = 0.5708$ W/(m·K) $\mathrm{Pr}_w = 11.16$

$\mathrm{Re}_d = \frac{\rho v d}{\mu} = 32\,944$ $\mathrm{Nu}_d = 248.3$ $k_w = 7087$ W/(m^2·K)

To compute h_o using Equation (T9.10a), the outer diameter of the insulation material must be found. Determine it by iteration by assuming a value of d_o, computing the value of h_o, and determining the value of d_o from Equation (42). If the assumed and computed values of d_o are close to each other, the correct solution has been obtained. Otherwise, recompute h_o using the newly computed value of d_o and repeat the process.

Assume $d_o = 0.05$ m. Properties of air at $t_f = 27$°C and 101.325 kPa are

$\rho = 1.176$ kg/m^3 $k = 0.025\,66$ W/(m·K) $\mu = 1.858 \times 10^{-5}$ (N·s)/m^2

$\mathrm{Pr} = 0.729$ $\beta = 0.003\,299$ (at 273.15 + 30 = 293.15 K)

$\mathrm{Ra} = 74\,574$ $\mathrm{Nu} = 7.223$ $h_o = 3.65$ W/(m^2·K)

$h_{ot} = 3.65 + 4.3 = 7.95$ W/(m^2·K)

Solving for d_o makes the left side of Equation (42) equal to the right side, and gives $d_o = 0.040\,03$ m. Now, using the new value of 0.040 03 m for the outer diameter, the new values of h_o and h_{ot} are 3.86 W/(m^2·K) and 8.20 W/(m^2·K), respectively. The updated value of d_o is 0.044 03 m. Repeating the process several times results in a final value of $d_o = 0.047\,17$ m. Thus, an outer diameter of 0.045 m (corresponding to an insulation radial thickness of 12.5 mm) keeps the outer surface temperature at 24.1°C, higher than the dew point. [Another method is to use Equation (42) to solve for t_o for values of d_o corresponding to available insulation thicknesses and using the insulation thickness that keeps t_o above the dew-point temperature.]

5. HEAT EXCHANGERS

Mean Temperature Difference Analysis

With heat transfer from one fluid to another (separated by a solid surface) flowing through a heat exchanger, the local temperature difference Δt varies along the flow path. Heat transfer rate may be calculated using

$$q = UA\,\Delta t_m \tag{43}$$

where U is the overall uniform heat transfer coefficient, A is the area associated with the coefficient U, and Δt_m is the appropriate mean temperature difference.

For a parallel or counterflow heat exchanger, the mean temperature difference is given by

$$\Delta t_m = (\Delta t_1 - \Delta t_2)/\ln(\Delta t_1/\Delta t_2) \tag{44}$$

where Δt_1 and Δt_2 are temperature differences between the fluids at each end of the heat exchanger; Δt_m is the **logarithmic mean temperature difference (LMTD)**. For the special case of $\Delta t_1 = \Delta t_2$ (possible only with a counterflow heat exchanger with equal capacities), which leads to an indeterminate form of Equation (44), $\Delta t_m = \Delta t_1 = \Delta t_2$.

Equation (44) for Δt_m is true only if the overall coefficient and the specific heat of the fluids are constant through the heat exchanger, and no heat losses occur (often well-approximated in practice). Parker et al. (1969) give a procedure for cases with variable overall coefficient U. For heat exchangers other than parallel and counterflow, a correction factor [see Incropera et al. (2007)] is needed for Equation (44) to obtain the correct mean temperature difference.

NTU-Effectiveness (ε) Analysis

Calculations using Equations (43) and (44) for Δt_m are convenient when inlet and outlet temperatures are known for both fluids. Often, however, the temperatures of fluids leaving the exchanger are unknown. To avoid trial-and-error calculations, the **NTU-ε method** uses three dimensionless parameters: effectiveness ε, number of transfer units (NTU), and capacity rate ratio c_r; the mean temperature difference in Equation (44) is not needed.

Heat exchanger effectiveness ε is the ratio of actual heat transfer rate to maximum possible heat transfer rate in a counterflow heat exchanger of infinite surface area with the same mass flow rates and inlet temperatures. The maximum possible heat transfer rate for hot fluid entering at t_{hi} and cold fluid entering at t_{ci} is

$$q_{max} = C_{min}(t_{hi} - t_{ci}) \tag{45}$$

where C_{min} is the smaller of the hot $[C_h = (\dot{m} c_p)_h]$ and cold $[C_c = (\dot{m} c_p)_h]$ fluid capacity rates, W/K; C_{max} is the larger. The actual heat transfer rate is

$$q = \varepsilon q_{max} \tag{46}$$

For a given exchanger type, heat transfer effectiveness can generally be expressed as a function of the **number of transfer units (NTU)** and the **capacity rate ratio c_r**:

$$\varepsilon = f(\mathrm{NTU}, c_r, \text{Flow arrangement}) \tag{47}$$

where

$\mathrm{NTU} = UA/C_{min}$

$c_r = C_{min}/C_{max}$

Effectiveness is independent of exchanger inlet temperatures. For any exchanger in which c_r is zero (where one fluid undergoing a phase change, as in a condenser or evaporator, has an effective $c_p = \infty$), the effectiveness is

$$\varepsilon = 1 - \exp(-\mathrm{NTU}) \qquad c_r = 0 \tag{48}$$

The mean temperature difference in Equation (44) is then given by

$$\Delta t_m = \frac{(t_{hi} - t_{ci})\varepsilon}{\mathrm{NTU}} \tag{49}$$

After finding the heat transfer rate q, exit temperatures for constant-density fluids are found from

$$|t_e - t_i| = \frac{q}{\dot{m} c_p} \tag{50}$$

Effectiveness for selected flow arrangements are given in Table 10.

Afgan and Schlunder (1974), Incropera, et al. (2007), and Kays and London (1984) present graphical representations for convenience. NTUs as a function of ε expressions are available in Incropera et al. (2007).

Example 13. Flue gases from a gas-fired furnace are used to heat water in a 5 m long counterflow, double-pipe heat exchanger. Water enters the inner, thin-walled 40 mm diameter pipe at 40°C with a velocity of 0.5 m/s. Flue gases enter the annular space with a mass flow rate of 0.12 kg/s at 200°C. To increase the heat transfer rate to the gases, 16 rectangular axial copper fins are attached to the outer surface of the inner pipe. Each fin is 60 mm high (radial height) and 1 mm thick, as shown in Figure 24. The gas-side surface heat transfer coefficient is 115 W/(m^2·K). Find the heat transfer rate and the exit temperatures of the gases and water.

The heat exchanger has the following properties:

Water in the pipe $t_{ci} = 40$°C $v_c = 0.5$ m/s

Gases $t_{hi} = 200$°C $m_h = 0.12$ kg/s

Length of heat exchanger $L_{tube} = 5$ m $d = 0.04$ m $L = 0.06$ m

$t = 0.001$ m N = number of fins = 16

Solution: The heat transfer rate is computed using Equations (45) and (46), and exit temperatures from Equation (50). To find the heat transfer rates, UA and ε are needed.

Table 10 Equations for Computing Heat Exchanger Effectiveness, N = NTU

Flow Configuration	Effectiveness ε	Comments	
Parallel flow	$\frac{1-\exp[-N(1+c_r)]}{1+c_r}$		(T10.1)
Counterflow	$\frac{1-\exp[-N(1-c_r)]}{1-c_r\exp[-N(1-c_r)]}$	$c_r \neq 1$	(T10.2)
	$\frac{N}{1+N}$	$c_r = 1$	(T10.3)
Shell-and-tube (one-shell pass, 2, 4, etc. tube passes)	$\frac{2}{1+c_r+a(1+e^{-aN})/(1-e^{-aN})}$	$a = \sqrt{1+c_r^2}$	(T10.4)
Shell-and-tube (n-shell pass, 2n, 4n, etc. tube passes)	$\left[\left(\frac{1-\varepsilon_1 c_r}{1-\varepsilon_1}\right)^n - 1\right]\left[\left(\frac{1-\varepsilon_1 c_r}{1-\varepsilon_1}\right)^n - c_r\right]^{-1}$	ε_1 = effectiveness of one-shell pass shell-and-tube heat exchanger	(T10.5)
Cross-flow (single phase)			
Both fluids unmixed	$1-\exp\left(\frac{\gamma N^{0.22}}{c_r}\right)$	$\gamma = \exp(-c_r N^{0.78}) - 1$	(T10.6)
C_{max} (mixed), C_{min} (unmixed)	$\frac{1-\exp(-c_r\gamma)}{c_r}$	$\gamma = 1-\exp(-N)$	(T10.7)
C_{max} (unmixed), C_{min} (mixed)	$1-\exp(-\gamma/c_r)$	$\gamma = 1-\exp(-Nc_r)$	(T10.8)
Both fluids mixed	$\frac{N}{N/(1-e^{-N}) + c_r N/(1-e^{-Nc_r}) - 1}$		(T10.9)
All exchangers with $c_r = 0$	$1-\exp(-N)$		(T10.10)

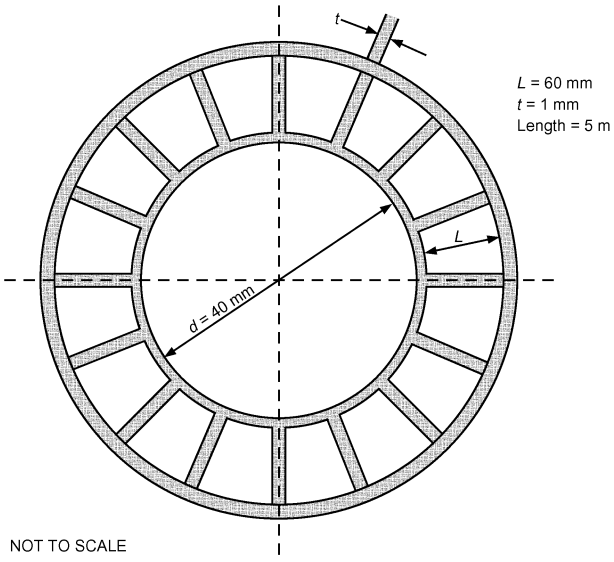

Fig. 24 Cross Section of Double-Pipe Heat Exchanger in Example 13

$$\frac{1}{UA} = \frac{1}{(\phi_s hA)_o} + \frac{1}{(hA)_i}$$

where

h_i = convective heat transfer coefficient on water side
h_o = gas-side heat transfer coefficient
ϕ_s = surface effectiveness = $(A_{uf} + A_f\phi)/A_o$
ϕ = fin efficiency
A_{uf} = surface area of unfinned surface = $L_{tube}(\pi d - Nt) = 0.548$ m^2
A_f = fin surface area = $2LNL_{tube} = 9.6$ m^2
$A_o = A_{uf} + A_f = 10.15$ m^2
$A_i = \pi d L_{tube} = 0.628$ m^2

Step 1. Find h_i using Equation (T8.6). Properties of water at an assumed mean temperature of 45°C are

$\rho = 990.4$ kg/m^3 $c_{pc} = 4181$ J/(kg·K) $\mu = 5.964 \times 10^{-4}$ (N·s)/m^2
$k = 0.6376$ W/(m·K) Pr = 3.91

$$\text{Re} = \frac{\rho v_c d}{\mu} = \frac{990.4 \times 0.5 \times 0.04}{5.964 \times 10^{-4}} = 33\,213$$

$$f_s/2 = [1.58\ln(\text{Re}) - 3.28]^{-2}/2 = (1.58\ln 33\,213 - 3.28)^{-2}/2 = 0.002\,88$$

$$\text{Nu}_d = \frac{0.002\,88 \times (33\,213 - 1000) \times 3.91}{1 + 12.7 \times (0.002\,88)^{1/2} \times (3.91^{2/3} - 1)} = 180.4$$

$$h_i = \frac{180.4 \times 0.6376}{0.04} = 2876 \text{ W/(m}^2\cdot\text{K)}$$

Step 2. Compute fin efficiency ϕ and surface effectiveness ϕ_s. For a rectangular fin with the end of the fin not exposed,

$$\phi = \frac{\tanh(mL)}{mL}$$

For copper, $k = 401$ W/(m·K).

$$mL = (2h_o/kt)^{1/2}L = [(2 \times 115)/(401 \times 0.001)]^{1/2}(0.06) = 1.44$$

$$\phi = \frac{\tanh 1.44}{1.44} = 0.62$$

$$\phi_s = (A_{uf} + \phi A_f)/A_0 = (0.548 + 0.62 \times 9.6)/10.15 = 0.64$$

Step 3. Find heat exchanger effectiveness. For air at an assumed mean temperature of 175°C, $c_{ph} = 1018$ J/(kg·K).

$$C_h = \dot{m}_h c_{ph} = 0.12 \times 1018 = 122.2 \text{ W/K}$$

$$\dot{m}_c = \rho v_c \pi d^2/4 = (990.4 \times 0.5 \times \pi \times 0.04^2)/4 = 0.6223 \text{ kg/s}$$

$$C_c = \dot{m}_c c_{pc} = 0.6223 \times 4181 = 2602 \text{ W/K}$$

$$c_r = C_{min}/C_{max} = 122.2/2602 = 0.04696$$

Licensed for single user. © 2021 ASHRAE, Inc.

$$UA = [1/(0.64 \times 115 \times 10.15) + 1/(2876 \times 0.628)]^{-1} = 528.5 \text{ W/K}$$

$$\text{NTU} = UA/C_{min} = 528.5/122.2 = 4.32$$

From Equation (T10.2),

$$\varepsilon = \frac{1 - \exp[-N(1 - c_r)]}{1 - c_r \exp[-N(1 - c_r)]}$$

$$= \frac{1 - \exp[-4.24 \times (1 - 0.046\ 96)]}{1 - 0.046\ 96 \times \exp[-4.24 \times (1 - 0.046\ 96)]} = 0.983$$

Step 4. Find heat transfer rate:

$$q_{max} = C_{min} \times (t_{hi} - t_{ci}) = 122.2 \times (200 - 40) = 19\ 552 \text{ W}$$

$$q = \varepsilon q_{max} = 0.985 \times 19\ 552 = 19\ 255 \text{ W}$$

Step 5. Find exit temperatures:

$$t_{he} = t_{hi} - \frac{q}{C_h} = 200 - \frac{19\ 255}{122.2} = 42.4°\text{C}$$

$$t_{ce} = t_{ci} + \frac{q}{C_c} = 40 + \frac{19\ 255}{2602} = 47.4°\text{C}$$

The mean temperature of water now is 43.7°C. The properties of water at this temperature are not very different from those at the assumed value of 45°C. The only property of air that needs to be updated is the specific heat, which at the updated mean temperature of 121°C is 1011 J/(kg·K), which is not very different from the assumed value of 1018 J/(kg·K). Therefore, no further iteration is necessary.

Plate Heat Exchangers

Plate heat exchangers (PHEs) are used regularly in HVAC&R. The three main types of plate exchangers are plate-and-frame (gasket or semiwelded), compact brazed (CBE), and shell-and-plate. The basic plate geometry is shown in Figure 25.

Plate Geometry. Different geometric parameters of a plate are defined as follows (Figure 25):

- **Chevron angle** β varies between 22 and 65°. This angle also defines the thermal hydraulic softness (low thermal efficiency and pressure drop) and hardness (high thermal efficiency and pressure drop).
- **Enlargement factor** ϕ is the ratio of developed length to protracted length.
- **Mean flow channel gap *b*** is the actual gap available for the flow: $b = p - t$.
- **Channel flow area A_x** is the actual flow area: $A_x = bw$.
- **Channel equivalent diameter d_e** is defined as $d_e = 4A_x/P$, where $P = 2(b + \phi w) = 2\phi w$, because $b << w$; therefore, $d_e = 2b/\phi$.

Heat Transfer and Pressure Drop. Table 11 (Ayub 2003) shows correlations for single-phase flow. For quick calculations with water, the correlation by Troupe et al. (1960) is recommended. For more accurate results, the other correlations shown are appropriate.

Example 14. A plate exchanger cools 40 kg/s of 90°C beer wort by 40 kg/s of water at 20°C. The heat exchanger dimensions are $L_p = 1$ m, $w = 0.5$ m, $p = 10$ mm, $t = 1$ mm, $\beta = 45°$, and $\phi = 1.24$. There are $N_p = 100$ plates. What is the rate of heat transfer and exit temperature of the wort? Assume the wort has the properties of water. Use $k_{plate} = 50$ W/(m·K) for the plates.

Solution: The Heavner et al. (1993) correlation in Table 11 is used. It is assumed the wort is cooled to 50°C, and its average bulk temperature is 70°C. The water is assumed to be heated to 60°C, and its average bulk temperature is 40°C. The plate temperature for both fluids is assumed to be 55°C. The needed properties at these temperatures are looked up [e.g., in Wasmund (1975)] for wort at 70°C: $\rho = 978$ kg/m^3, $\mu = 4.04 \times 10^{-4}$ kg/(m·s), $c_p = 4.19$ kJ/(kg·K), $k = 0.663$ W/(m·K), and Pr = 2.56. For water at 40°C, the properties are $\rho = 992$ kg/m^3, $\mu = 6.53 \times 10^{-4}$ kg/(m·s), $c_p = 4.18$ kJ/(kg·K), $k = 0.631$ W/(m·K), and Pr = 4.34. For the wall at 55°C, $\mu_w = 5.04 \times 10^{-4}$ kg/(m·s).

Values based on the heat exchanger dimensions are $b = p - t = 9$ mm, $A_x = bw = (0.009 \text{ m})(0.5 \text{ m}) = 0.045$ m^2, and $d_e = 14.52$ mm. Heat transfer area $A_{HX} = N_p L_p w \phi = 62.0$ m^2. Flow cross section for both fluids is $A_c = (N_p/2)A_x = 0.225$ m^2. From the table for the correlation at $\beta = 45°$, $C_1 = 0.195$ and $m = 0.692$. For both fluids, $G = m/A_c = 177.8$ kg/(m^2·s).

The heat transfer coefficient on the wort side is determined first:

$$\text{Re}_t = Gd_e/\mu = 6388$$

$$\text{Nu} = C_1 \phi^{1-m} \text{Re}^m \text{Pr}^{0.5} (\mu/\mu_w)^{0.17} = 138.0$$

$$h_{wort} = \text{Nu}k/d_e = 5083 \text{ W/(m}^2\text{·K)}$$

Similarly, the heat transfer coefficient for the water is determined:

$$\text{Re}_t = Gd_e/\mu = 3952$$

$$\text{Nu} = C_1 \phi^{1-m} \text{Re}^m \text{Pr}^{0.5} (\mu/\mu_w)^{0.17} = 107.4$$

$$h_{water} = \text{Nu}k/d_e = 3765 \text{ W/(m}^2\text{·K)}$$

If no fouling is assumed,

$$U = (1/h_{wort} + 1/h_{water} + t/k_{plate})^{-1} = 2073 \text{ W/(m}^2\text{·K)}$$

$$UA_{HX} = 128\ 540 \text{ W/K}$$

$$\text{NTU} = UA_{HX}/(mc_p)_{min} = UA_{HX}/(mc_p)_{water} = 0.769$$

$$c_r = (mc_p)_{water}/(mc_p)_{wort} = 0.998$$

For a counterflow heat exchanger, Equation (46) gives $\varepsilon = 0.435$. Then,

$$q = \varepsilon(mc_p)_{min}(t_{wort,\,in} - t_{water,\,in}) = 5.09 \times 10^6 \text{ W}$$

$$t_{wort,\,out} = t_{wort,\,in} - q/(mc_p)_{wort} = 59.6°\text{C}$$

Heat Exchanger Transients

Determining the transient behavior of heat exchangers is increasingly important in evaluating the dynamic behavior of heating and air-conditioning systems. Many studies of counterflow and parallel flow heat exchangers have been conducted; some are listed in the Bibliography.

6. HEAT TRANSFER AUGMENTATION

As discussed by Bergles (1998, 2001), techniques applied to augment (enhance) heat transfer can be classified as passive (requiring no direct application of external power) or active (requiring external power). Passive techniques include rough surfaces, extended surfaces, displaced promoters, and vortex flow devices. Active techniques include mechanical aids, surface or fluid vibration, and electrostatic fields. The effectiveness of a given augmentation technique depends largely on the mode of heat transfer or type of heat exchanger to which it is applied.

When augmentation is used, the dominant thermal resistances in the circuit should be considered. Do not invest in reducing an already low thermal resistance or increasing an already high heat transfer coefficient. Also, heat exchangers with a high NTU [number of heat exchanger transfer units; see Equation (47)] benefit little from augmentation. Finally, the increased friction factor that usually accompanies heat transfer augmentation must also be considered.

Passive Techniques

Finned-Tube Coils. Heat transfer coefficients for finned coils follow the basic equations of convection, condensation, and evaporation. The fin arrangement affects the values of constants and exponential powers in the equations. It is generally necessary to refer to test data for the exact coefficients.

For natural-convection finned coils (gravity coils), approximate coefficients can be obtained by considering the coil to be made of tubular and vertical fin surfaces at different temperatures and then applying the natural-convection equations to each. This is difficult because the natural-convection coefficient depends on the temperature difference, which varies at different points on the fin.

Fin efficiency should be high (80 to 90%) for optimum natural-convection heat transfer. A low fin efficiency reduces temperatures near the tip. This reduces Δt near the tip and also the coefficient h, which in natural convection depends on Δt. The coefficient of heat transfer also decreases as fin spacing decreases because of interfering

Licensed for single user. © 2021 ASHRAE, Inc.

convection currents from adjacent fins and reduced free-flow passage; 50 to 100 mm spacing is common. Generally, high coefficients result from large temperature differences and small flow restriction.

Edwards and Chaddock (1963) give coefficients for several circular fin-on-tube arrangements, using fin spacing δ as the characteristic length and in the form $Nu = f(Ra_\delta, \delta/D_o)$, where D_o is the fin diameter.

Forced-convection finned coils are used extensively in a wide variety of equipment. Fin efficiency for optimum performance is smaller than that for gravity coils because the forced-convection coefficient is almost independent of the temperature difference between surface and fluid. Very low fin efficiencies should be avoided because an inefficient surface gives a high (uneconomical) pressure drop. An efficiency of 70 to 90% is often used.

As fin spacing is decreased to obtain a large surface area for heat transfer, the coefficient generally increases because of higher air velocity between fins at the same face velocity and reduced equivalent diameter. The limit is reached when the boundary layer formed on one fin surface (see Figure 19) begins to interfere with the boundary layer formed on the adjacent fin surface, resulting in a decrease of the heat transfer coefficient, which may offset the advantage of larger surface area.

Selection of fin spacing for forced-convection finned coils usually depends on economic and practical considerations, such as fouling, frost formation, condensate drainage, cost, weight, and volume. Fins for conventional coils generally are spaced 1.8 to 4.2 mm apart, except where factors such as frost formation necessitate wider spacing.

There are several ways to obtain higher coefficients with a given air velocity and surface, usually by creating air turbulence, generally with a higher pressure drop: (1) staggered tubes instead of in-line tubes for multiple-row coils; (2) artificial additional tubes, or collars or fingers made by forming the fin materials; (3) corrugated fins instead of plane fins; and (4) louvered or interrupted fins.

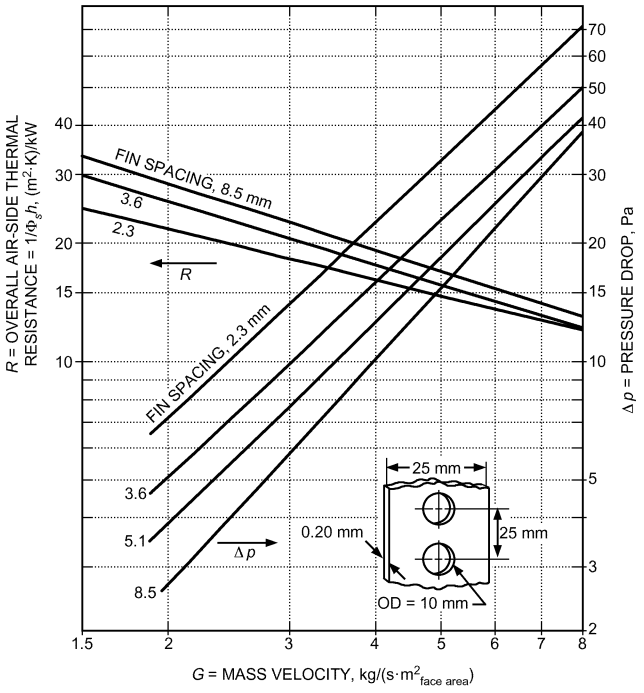

Fig. 26 Overall Air-Side Thermal Resistance and Pressure Drop for One-Row Coils
(Shepherd 1946)

Figure 26 shows data for one-row coils. Thermal resistances plotted include the temperature drop through the fins, based on one square metre of total external surface area.

Internal Enhancement. Several examples of tubes with internal roughness or fins are shown in Figure 27. Rough surfaces of the spiral repeated rib variety are widely used to improve in-tube heat transfer with water, as in flooded chillers. Roughness may be produced by spirally indenting the outer wall, forming the inner wall, or inserting coils. Longitudinal or spiral internal fins in tubes can be produced by extrusion or forming and substantially increase surface area. Efficiency of extruded fins can usually be taken as unity (see the section on Fin Efficiency). Twisted strips (vortex flow devices) can be inserted as original equipment or as a retrofit (Manglik and Bergles 2002). From a practical point of view, the twisted tape width should be such that the tape can be easily inserted or removed. Ayub and Al-Fahed (1993) discuss clearance between the twisted tape and tube inside dimension.

Microfin tubes (internally finned tubes with about 60 short fins around the circumference) are widely used in refrigerant evaporation and condensers. Because gas entering the condenser in vapor-compression refrigeration is superheated, a portion of the condenser that desuperheats the flow is single phase. Some data on single-phase performance of microfin tubes, showing considerably higher heat transfer coefficients than for plain tubes, are available [e.g., Al-Fahed et al. (1993); Khanpara et al. (1986)], but the upper Reynolds numbers of about 10 000 are lower than those found in practice. ASHRAE research [e.g., Eckels (2003)] is addressing this deficiency.

The increased friction factor in microfin tubes may not require increased pumping power if the flow rate can be adjusted or the length of the heat exchanger reduced. Nelson and Bergles (1986) discuss performance evaluation criteria, especially for HVAC applications.

In chilled-water systems, fouling may, in some cases, seriously reduce the overall heat transfer coefficient U. In general, fouled enhanced tubes perform better than fouled plain tubes, as shown in studies of scaling caused by cooling tower water (Knudsen and Roy

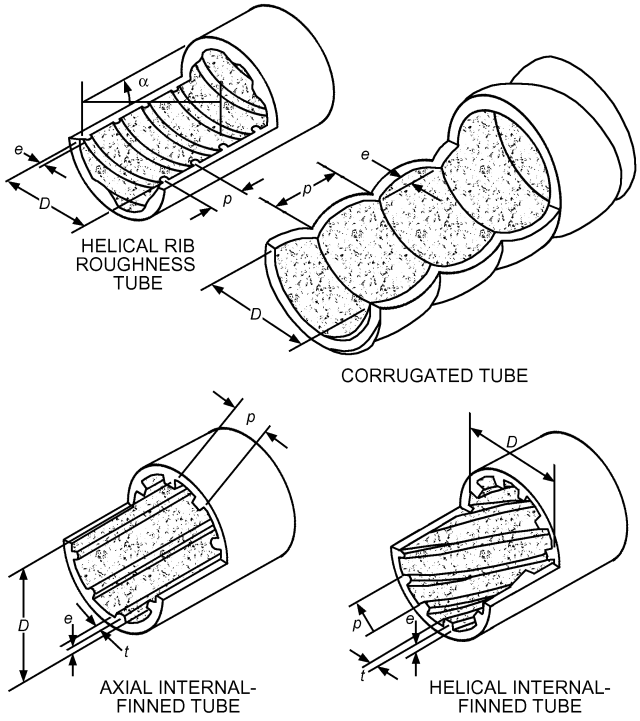

Fig. 27 Typical Tube-Side Enhancements

Licensed for single user. © 2021 ASHRAE, Inc.

1983) and particulate fouling (Somerscales et al. 1991). A comprehensive review of fouling with enhanced surfaces is presented by Somerscales and Bergles (1997).

Fire-tube boilers are frequently fitted with turbulators to improve the turbulent convective heat transfer coefficient (addressing the dominant thermal resistance). Also, because of high gas temperatures, radiation from the convectively heated insert to the tube wall can represent as much as 50% of the total heat transfer. (Note, however, that the magnitude of convective contribution decreases as the radiative contribution increases because of the reduced temperature difference.) Two commercial bent-strip inserts, a twisted-strip insert, and a simple bent-tab insert are depicted in Figure 28. Design equations for convection only are included in Table 12. Beckermann and Goldschmidt (1986) present procedures to include radiation, and Junkhan et al. (1985, 1988) give friction factor data and performance evaluations.

Enhanced Surfaces for Gases. Several such surfaces are depicted in Figure 29. The offset strip fin is an example of an interrupted fin that is often found in compact plate fin heat exchangers used for heat recovery from exhaust air. Design equations in Table 12 apply to laminar and transitional flow as well as to turbulent flow, which is a necessary feature because the small hydraulic diameter of these surfaces drives the Reynolds number down. Data for other surfaces (wavy, spine, louvered, etc.) are available in the References.

Microchannel Heat Exchangers. Microchannels for heat transfer enhancement are widely used, particularly for compact heat exchangers in automotive, aerospace, fuel cell, and high-flux electronic cooling applications. Bergles (1964) demonstrated the potential of narrow passages for heat transfer enhancement; more recent experimental and numerical work includes Adams et al. (1998), Costa et al. (1985), Kandlikar (2002), Ohadi et al. (2008), Pei et al. (2001), and Rin et al. (2006).

Compared with channels of normal size, microchannels have many advantages. When properly designed, they can offer substantially higher heat transfer rates (because of their greater heat transfer surface area per unit volume and a large surface-to-volume ratio) and reduced pressure drops and pumping power requirements when compared to conventional mini- and macrochannels. Optimum flow delivery to the channels and proper heat transfer surface/channel design is critical to optimum operation of microchannels (Ohadi et al. 2012). This feature allows heat exchangers to be compact and lightweight. Despite their thin walls, microchannels can withstand high operating pressures: for example, a microchannel with a hydraulic diameter of 0.8 mm and a wall thickness of 0.3 mm can easily withstand operating pressures of up to 14 MPa. This feature makes microchannels particularly suitable for use with high-pressure refrigerants such as carbon dioxide (CO_2). For high-flux electronics (with heat flux at 1 kW/cm^2 or higher), microchannels can provide cooling with small temperature gradients (Ohadi et al. 2008). Microchannels have been used for both single-phase and phase-change heat transfer applications.

Drawbacks of microchannels include large pressure drop, high cost of manufacture, dirt clogging, and flow maldistribution, especially for two-phase flows. Most of these weaknesses, however, may be solved by optimizing design of the surface and the heat exchanger manifold and feed system.

	$h_s = \frac{(k/D)(f_s/2)\mathrm{Re}\ \mathrm{Pr}}{1 + 12.7(f_s/2)^{1/2}(\mathrm{Pr}^{2/3} - 1)}$	
	$f_s = (1.58 \ln \mathrm{Re} - 3.28)^{-2}$	
Fins[b]	$\frac{hD_h}{k} = 0.023\ \mathrm{Pr}^{0.4}\left(\frac{GD_h}{\mu}\right)^{0.8}\left(\frac{A_F}{AF_i}\right)^{0.1}\left(\frac{A_i}{A}\right)^{0.5}(\sec\alpha)^3$	Note that, in computing Re for fins and twisted-strip inserts, there is allowance for reduced cross-sectional area.
	$f_h = 0.046\left(\frac{GD_h}{\mu}\right)^{-0.2}\left(\frac{A_F}{AF_i}\right)^{0.5}(\sec\alpha)^{0.75}$	
Twisted-strip inserts[c]	$\frac{(hd/k)}{(hd/k)_{y\to\infty}} = 1 + 0.769/y$	
	$\left(\frac{hd}{k}\right)_{y\to\infty} = 0.023\left(\frac{GD}{\mu}\right)^{0.8}\mathrm{Pr}^{0.4}\left(\frac{\pi}{\pi - 4\delta/d}\right)^{0.8}\left(\frac{\pi + 2 - 2\delta/d}{\pi - 4\delta/d}\right)^{0.2}\phi$	
	$\phi = (\mu_b/\mu_w)^n$	
	$n = 0.18$ for liquid heating, 0.30 for liquid cooling	
	$f = \frac{0.0791}{(GD/\mu)^{0.25}}\left(\frac{\pi}{\pi - 4\delta/d}\right)^{1.75}\left(\frac{\pi + 2 - 2\delta/d}{\pi - 4\delta/d}\right)^{1.25}\left(1 + \frac{2.752}{y^{1.29}}\right)$	
II. Turbulent in-tube flow of gases		
Bent-strip inserts[d]	$\frac{hD}{k}\left(\frac{T_w}{T_b}\right)^{0.45} = 0.258\left(\frac{GD}{\mu}\right)^{0.6}$ or $\frac{hD}{k}\left(\frac{T_w}{T_b}\right)^{0.45} = 0.208\left(\frac{GD}{\mu}\right)^{0.63}$	Respectively, for configurations shown in Figure 28.
Twisted-strip inserts[d]	$\frac{hD}{k}\left(\frac{T_w}{T_b}\right)^{0.45} = 0.122\left(\frac{GD}{\mu}\right)^{0.65}$	
Bent-tab inserts[d]	$\frac{hD}{k}\left(\frac{T_w}{T_b}\right)^{0.45} = 0.406\left(\frac{GD}{\mu}\right)^{0.54}$	Note that, in computing Re, there is no allowance for flow blockage of the insert.
III. Offset strip fins for plate-fin heat exchangers[e]		
	$\frac{h}{c_p G} = 0.6522\left(\frac{GD_h}{\mu}\right)^{-0.5403}\alpha^{-0.1541}\delta^{0.1499}\gamma^{-0.0678}\left[1 + 5.269 \times 10^{-5}\left(\frac{GD_h}{\mu}\right)^{1.340}\alpha^{0.504}\delta^{0.456}\gamma^{-1.055}\right]^{0.1}$	
	$f_h = 9.6243\left(\frac{GD_h}{\mu}\right)^{-0.7422}\alpha^{-0.1856}\delta^{-0.3053}\gamma^{-0.2659}\left[1 + 7.669 \times 10^{-8}\left(\frac{GD_h}{\mu}\right)^{4.429}\alpha^{0.920}\delta^{3.767}\gamma^{0.236}\right]^{0.1}$	
	h/c_pG, f_h, and GD_h/μ are based on the hydraulic mean diameter given by $D_h = 4shl/[2(sl + hl + th) + ts]$	

Sources: [a]Ravigururajan and Bergles (1985), [b]Carnavos (1979), [c]Manglik and Bergles (1993), [d]Junkhan et al. (1985), [e]Manglik and Bergles (1990).

Microchannels are fabricated by a variety of processes, depending on the dimensions and plate material (e.g., metals, plastics, silicon). Conventional machining and electrical discharge machining are two typical options; semiconductor fabrication processes are appropriate for microchannel fabrication in chip-cooling applications. Using microfabrication techniques developed by the electronics industry, three-dimensional structures as small as 0.1 μm long can be manufactured.

Fluid flow and heat transfer in microchannels may be substantially different from those encountered in the conventional tubes. Early research indicates that deviations might be particularly important for microchannels with hydraulic diameters less than 100 μm.

Recent Progress. The automotive, aerospace, and cryogenic industries have made major progress in compact evaporator development. Thermal duty and energy efficiency have substantially

Licensed for single user. © 2021 ASHRAE, Inc.

increased, and space constraints have become more important, encouraging greater heat transfer rates per unit volume. The hot side of the evaporators in these applications is generally air, gas, or a condensing vapor. Air-side fin geometry improvements derive from increased heat transfer coefficients and greater surface area densities. To decrease the air-side heat transfer resistance, more aggressive fin designs have been used on the evaporating side, resulting in narrower flow passages. The narrow refrigerant channels with large aspect ratios are brazed in small cross-ribbed sections to improve flow distribution along the width of the channels. Major recent changes in designs involve individual, small-hydraulic-diameter flow passages, arranged in multichannel configuration for the evaporating fluid. Figure 30 shows a plate-fin evaporator geometry widely used in compact refrigerant evaporators.

The refrigerant-side passages are made from two plates brazed together, and air-side fins are placed between two refrigerant microchannel flow passages. Figure 31 depicts two representative microchannel geometries widely used in the compact heat exchanger industry, with corresponding approximate nominal dimensions provided in Table 13 (Zhao et al. 2000).

Plastic heat exchangers have been suggested for HVAC applications (Pescod 1980) and are being manufactured for refrigerated sea water (RSW) applications. They can be made of materials impervious to corrosion [e.g., by acidic condensate when cooling a gaseous stream (flue gas heat recovery)], and are easily manufactured with enhanced surfaces. Several companies now offer heat exchangers in plastic, including various enhancements.

Active Techniques

Unlike passive techniques, active techniques require external power to sustain the enhancement mechanism.

Table 14 lists the more common active heat transfer augmentation techniques and the corresponding heat transfer mode believed most applicable to the particular technique. Various active techniques and their world-wide status are listed in Table 15. Except for mechanical aids, which are universally used for selected applications, most other active techniques have found limited commercial applications and are still in development. However, with increasing demand for smart and miniaturized thermal management systems, actively controlled heat transfer augmentation techniques will soon become necessary for some advanced thermal management systems. All-electric ships, airplanes, and cars use electronics for propulsion, auxiliary systems, sensors, countermeasures, and other system needs. Advances in power electronics and control systems will allow optimized and tactical allocation of total installed power among system components.

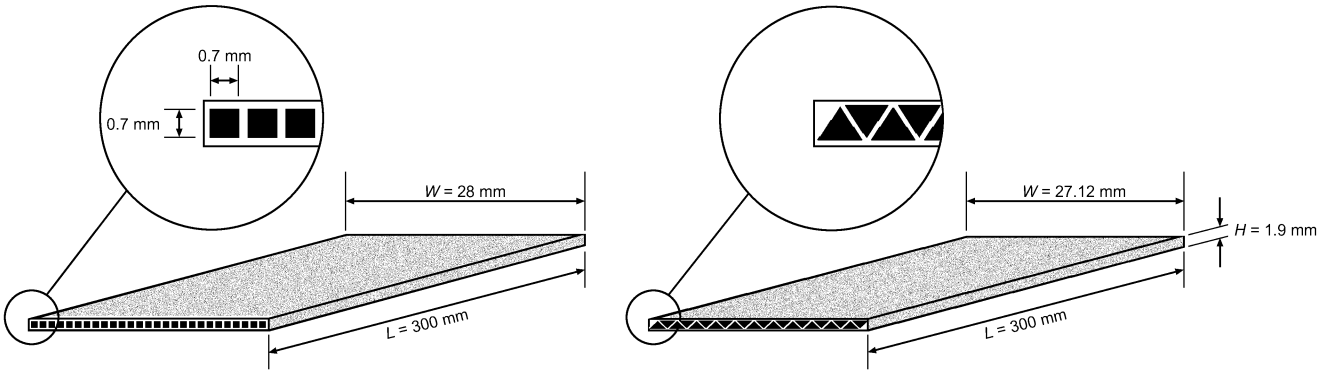
Table 15 Worldwide Status of Active Techniques



Technique	Country or Countries
Mechanical aids	Universally used in selected applications (e.g., fluid mixers, liquid injection jets)
Surface vibration	Most recent work in United States; not significant
Fluid vibration	Sweden; mostly used for sonic cleaning
Electrostatic/electrohydrodynamic	Japan, United States, United Kingdom; successful prototypes demonstrated
Other electrical methods	United Kingdom, France, United States
Suction/injection	No recent significant developments
Jet impingement	France, United States; high-temperature units and aerospace applications
Rotation	United States (industry), United Kingdom (R&D)
Induced flow	United States; particularly combustion

This in turn will require smart (online/on-demand), compact heat exchangers and thermal management systems that can communicate and respond to transient system needs. This section briefly overviews active techniques and recent progress; for additional details, see Ohadi et al. (1996).

Mechanical Aids. Augmentation by mechanical aids involves stirring the fluid mechanically. Heat exchangers that use mechanical enhancements are often called **mechanically assisted heat exchangers**. Stirrers and mixers that scrape the surface are extensively used in chemical processing of highly viscous fluids, such as blending a flow of highly viscous plastic with air. Surface scraping can also be applied to duct flow of gases. Hagge and Junkhan (1974) reported tenfold improvement in the heat transfer coefficient for laminar airflow over a flat plate. Table 16 lists selected works on mechanical aids, suction, and injection.

Injection. This method involves supplying a gas to a flowing liquid through a porous heat transfer surface or injecting a fluid of a similar type upstream of the heat transfer test section. Injected

A. MICROCHANNEL I B. MICROCHANNEL II

Fig. 31 Microchannel Dimensions

bubbles produce an agitation similar to that of nucleate boiling. Gose et al. (1957) bubbled gas through sintered or drilled heated surfaces and found that the heat transfer coefficient increased 500% in laminar flow and about 50% in turbulent flow. Tauscher et al. (1970) demonstrated up to a fivefold increase in local heat transfer coefficients by injecting a similar fluid into a turbulent tube flow, but the effect dies out at a length-to-diameter ratio of 10. Practical application of injection appears to be rather limited because of difficulty in cost-effectively supplying and removing the injection fluid.

Suction. The suction method involves removing fluid through a porous heated surface, thus reducing heat/mass transfer resistance at the surface. Kinney (1968) and Kinney and Sparrow (1970) reported that applying suction at the surface increased heat transfer coefficients for laminar film and turbulent flows, respectively. Jeng et al. (1995) conducted experiments on a vertical parallel channel with asymmetric, isothermal walls. A porous wall segment was embedded in a segment of the test section wall, and enhancement occurred as hot air was sucked from the channel. The local heat transfer coefficient increased with increasing porosity. The maximum heat transfer enhancement obtained was 140%.

Fluid or Surface Vibration. Fluid or surface vibrations occur naturally in most heat exchangers; however, naturally occurring vibration is rarely factored into thermal design. Vibration equipment is expensive, and power consumption is high. Depending on frequency and amplitude of vibration, forced convection from a wire to air is enhanced by up to 300% (Nesis et al. 1994). Using standing waves in a fluid reduced input power by 75% compared with a fan that provided the same heat transfer rate (Woods 1992). Lower frequencies are preferable because they consume less power and are less harmful to users' hearing. Vibration has not found industrial applications at this stage of development.

Rotation. Rotation heat transfer enhancement occurs naturally in rotating electrical machinery, gas turbine blades, and some other equipment. The rotating evaporator, rotating heat pipe, high-performance distillation column, and Rotex absorption cycle heat pump are typical examples of previous work in this area. In rotating evaporators, the rotation effectively distributes liquid on the outer part of the rotating surface. Rotating the heat transfer surface also seems promising for effectively removing condensate and decreasing liquid film thickness. Heat transfer coefficients have been substantially increased by using centrifugal force, which may be several times greater than the gravity force.

As shown in Table 17, heat transfer enhancement varies from slight improvement up to 450%, depending on the system and rotation speed. The rotation technique is of particular interest for use in two-phase flows, particularly in boiling and condensation. This technique is not effective in gas-to-gas heat recovery mode in laminar flow, but its application is more likely in turbulent flow. High power consumption, sealing and vibration problems, moving parts, and the expensive equipment required for rotation are some of this technique's drawbacks.

Electrohydrodynamics. Electrohydrodynamic (EHD) enhancement of single-phase heat transfer refers to coupling an electric field with the fluid field in a dielectric fluid medium. The net effect is production of secondary motions that destabilize the thermal boundary layer near the heat transfer surface, leading to heat transfer coefficients that are often an order of magnitude higher than those achievable by most conventional enhancement techniques. EHD heat

transfer enhancement has applicability to both single-phase and phase-change heat transfer processes, although only enhancement of single-phase flows is discussed here.

Selected work in EHD enhancement of single-phase flow is shown in Table 18. High enhancement magnitudes have been found for single-phase air and liquid flows. However, high enhancement magnitude is not enough to warrant practical implementation. EHD electrodes must be compatible with cost-effective, mass-production technologies, and power consumption must be kept low, to minimize the required power supply cost and complexity.

The following brief overview discusses recent work on EHD enhancement of air-side heat transfer; additional details are in Ohadi et al. (2001).

EHD Air-Side Heat Transfer Augmentation. In a typical liquid-to-air heat exchanger, air-side thermal resistance is often the limiting factor to improving the overall heat transfer coefficient. Electrohydrodynamic enhancement of air-side heat transfer involves ionizing air molecules under a high-voltage, low-current electric field, leading to generation of secondary motions that are known as **corona** or **ionic wind**, generated between the charged electrode and receiving (ground) electrode. Typical wind velocities of 1 to 3 m/s have been verified experimentally. Studies of this enhancement method include Ohadi et al. (1991), who studied laminar and turbulent forced-convection heat transfer of air in tube flow, and Owsenek and Seyed-Yagoobi (1995), who investigated heat transfer augmentation of natural convection with the corona wind effect. Other studies are documented in Ohadi et al. (2001). The general finding has been that corona wind is effective for Reynolds numbers up to transitional values, 2300 or less, and becomes less effective as Re increases. At high Reynolds numbers, turbulence-induced effects overwhelm the corona wind effect.

Most studies addressed EHD air-side enhancement in classical geometries, but recent work has focused on issues of practical significance. These include (1) EHD applicability in highly compact heat exchangers, (2) electrode designs to minimize power consumptions to avoid joule heating and costly power supply requirements, and (3) cost-effective mass production of EHD-enhanced surfaces.

Lawler et al. (2002) examined air-side enhancement of an air-to-air heat exchanger with 4.2 to 6.4 mm fin spacing. Unlike previous studies, this study investigated placing electrodes on the heat transfer surface itself, integrated into the surface as an embedded wire, thus avoiding suspended wires in the flow field. This arrangement

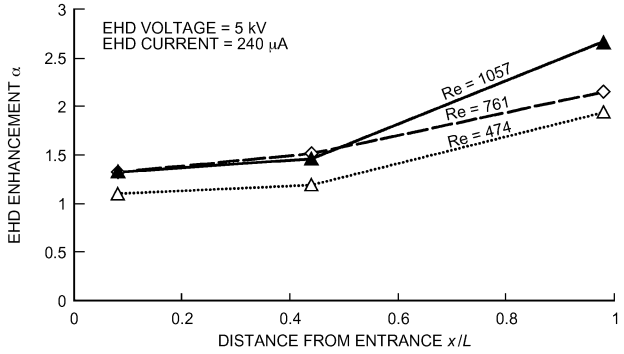

Fig. 32 Ratio of Heat Transfer Coefficient with EHD to Coefficient Without EHD as Function of Distance from Front of Module

could greatly simplify manufacturing/fabrication for EHD-enhanced embedded electrodes. Insulating materials (in this case, polyimide tape) were placed between the heat transfer surface and electrodes. The height of the channel (8 mm) represented typical heights used in passive metallic designs and prevented sparking between the electrodes and upper and lower channel walls.

Figure 32 shows the ratio of heat transfer coefficients (EHD/non-EHD) as a function of position in the module for three different Reynolds numbers. For nonentry regions of the duct, enhancement is 100 to 150% for Reynolds numbers above 400. Near the module entrance, EHD enhancement is reduced, probably because of the higher heat transfer coefficient in the entry region, before viscous and thermal boundary layers have been established.

Tests for a finned heat exchanger with 6 mm fin spacing obtained comparable enhancements for Reynolds numbers up to 4000. The results are shown in Figure 33. At higher Re, the effect of EHD enhancement diminishes, as turbulence-induced enhancements predominate.

EHD can also be used for other process control applications, including frost control, enhancing liquid/vapor separation for flow maldistribution control in heat exchangers, and oil separation in heat exchanger equipment. ASHRAE has recently sponsored three EHD research projects: (1) EHD-enhanced boiling of refrigerants (Seyed-Yagoobi 1997), (2) EHD frost control in HVAC&R equip-

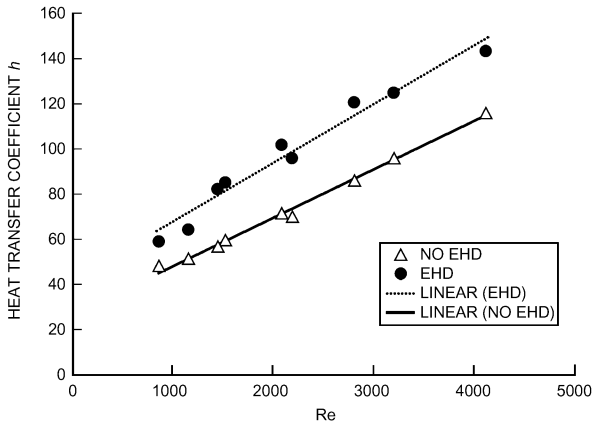

Fig. 33 Heat Transfer Coefficients (With and Without EHD) as Functions of Reynolds Number

ment (Ohadi 2002), and (3) EHD flow maldistribution control in heat exchangers (Seyed-Yagoobi and Feng 2005). Reports for these projects are available through ASHRAE headquarters.

7. SYMBOLS

A = surface area for heat transfer
A_F, A_x = cross-sectional flow area
b = flow channel gap
Bi = Biot number (hL/k)
C = conductance; fluid capacity rate
c = coefficient; constant
C_1, C_2 = Planck's law constants [see Equation (19)]
c_p = specific heat at constant pressure
c_r = capacity ratio
c_v = specific heat at constant volume
D = tube (inside) or rod diameter; diameter of vessel
d = diameter; prefix meaning differential
E = electric field
e = protuberance height
f = Fanning friction factor for single-phase flow; electric body force
F_{ij} = angle factor
Fo = Fourier number
G = mass velocity; irradiation; $\dot{m}/A_x$, in pipe Reynolds number (Table 12)
g = gravitational acceleration
Gr = Grashof number
Gz = Graetz number
H = height
h = heat transfer coefficient; offset strip fin height
I = modified Bessel function
J = radiosity
J_0 = Bessel function of the first kind, order zero
j = Colburn heat transfer factor
k = thermal conductivity
L = length; height of liquid film
l = length; length of one module of offset strip fins; liquid
M = mass; molecular mass
m = general exponent; inverse of Biot number
$\dot{m}$ = mass rate of flow
n = general number; ratio r/r_m (dimensionless distance); number of blades
NTU = number of exchanger heat transfer units
Nu = Nusselt number
P = perimeter
p = pressure; fin pitch; repeated rib pitch
Pr = Prandtl number
Q = volume flow rate
q = heat transfer rate
q'' = heat flux
R = thermal resistance; radius
r = radius
Ra = Rayleigh number (Gr Pr)
Re = pipe Reynolds number (GD/μ); film Reynolds number ($4\Gamma/h$)
Re* = rotary Reynolds number (D^2Np/h)
S = conduction shape factor
s = lateral spacing of offset fin strips
T = absolute temperature
t = temperature; fin thickness at base; plate thickness
U = overall heat transfer coefficient
V = linear velocity; volume
W = work; emissive power; fin dimension
w = wall; effective plate width
W_b = blackbody emissive power
W_λ = monochromatic emissive power
x, y, z = lengths along principal coordinate axes
Y = temperature ratio
y = one-half diametrical pitch of a twisted tape: length of 180° revolution/tube diameter

Greek

α = thermal diffusivity = $k/\rho c_p$; absorptivity; spiral angle for helical fins; aspect ratio of offset strip fins, s/h; enhancement factor: ratio of enhanced to unenhanced heat transfer coefficient (conditions remaining the same)
β = coefficient of thermal expansion; contact angle of rib profile; chevron angle, °
β^* = chevron angle ratio, (β/β_{min})
β_{min} = smaller of two chevron angles
Γ = mass flow of liquid per unit length
γ = ratio, t/s
δ = distance between fins; ratio t/l; thickness of twisted tape
ε = hemispherical emissivity; exchanger heat transfer effectiveness; dielectric constant
λ = wavelength; corrugation pitch
μ = absolute viscosity
ν = kinematic viscosity (μ/ρ), m^2/s
ϖ = eigenvalue
ρ = density; reflectance
σ = Stefan-Boltzmann constant, 5.67×10^{-8} W/($m^2 \cdot K^4$)
τ = time; transmissivity
Φ = dimensionless fin resistance; Φ_{max} is maximum limiting value of Φ
ϕ = fin efficiency; angle; temperature correction factor; ratio of developed length to protracted length

Subscripts

a = augmented
b = blackbody; based on bulk fluid temperature
c = convection; critical; cold (fluid); cross section
cr = critical
e = equivalent; environment; exit
f = film; fin; final
g = gas
gen = internal generation
h = horizontal; hot (fluid); hydraulic
i = inlet; inside; particular surface (radiation); based on maximum inside (envelope) diameter
if = interface
iso = isothermal conditions
j = particular surface (radiation)
k = particular surface (radiation)
L = thickness
l = liquid
m = mean
n = counter variable
o = outside; outlet; overall; at base of fin
p = prime heat transfer surface; plate
r = radiation; root (fin); reduced
s = surface; secondary heat transfer surface; straight or plain; accounting for flow blockage of twisted tape
st = static (pressure)
t = temperature; terminal temperature; tip (fin)
uf = unfinned
v = vapor; vertical

Licensed for single user. © 2021 ASHRAE, Inc.

W = width
wet = wetted
w = wall; water; or wafer
λ = monochromatic

CHAPTER 5

TWO-PHASE FLOW

Boiling 5.1
Condensing 5.11
Pressure Drop 5.15
Symbols 5.20

TWO-phase flow is encountered extensively in the HVAC&R industries. A combination of liquid and vapor refrigerant exists in flooded coolers, direct-expansion coolers, thermosiphon coolers, brazed and gasketed plate evaporators and condensers, and tube-in-tube evaporators and condensers, as well as in air-cooled evaporators and condensers. In heating system pipes, steam and liquid water may both be present. Because the hydrodynamic and heat transfer aspects of two-phase flow are not as well understood as those of single-phase flow, no comprehensive model has yet been created to predict pressure drops or heat transfer rates. Instead, the correlations are for specific thermal and hydrodynamic operating conditions.

This chapter introduces two-phase flow and heat transfer processes of pure substances and refrigerant mixtures. Thus, some multiphase processes that are important to HVAC&R applications are not discussed here. The 2020 *ASHRAE Handbook—HVAC Systems and Equipment* provides information on several such applications, including humidification (Chapter 22), particulate contaminants (Chapter 29), cooling towers (Chapter 40), and evaporative air cooling (Chapter 41). See Chapter 18 of the 2018 *ASHRAE Handbook—Refrigeration* for information on absorption cooling, heating, and refrigeration processes.

1. BOILING

Two-phase heat and mass transport are characterized by various flow and thermal regimes and whether vaporization occurs under natural convection or in forced flow. Unlike single-phase flow systems, the heat transfer coefficient for a two-phase mixture depends on the flow regime, thermodynamic and transport properties of both vapor and liquid, roughness of heating surface, wetting characteristics of the surface/liquid pair, orientation of the heat transfer surface, and other parameters. Therefore, it is necessary to consider each flow and boiling regime separately to determine the heat transfer coefficient.

Although much progress has been made in the past few decades, accurate data defining regime limits and determining the effects of various parameters in geometries and surfaces of practical significance are still limited to empirical correlations for select surfaces and working fluids and for specified operational ranges for which the data have been collected.

Boiling and Pool Boiling in Natural Convection Systems

Regimes of Boiling. The different regimes of pool boiling described by Farber and Scorah (1948) verified those suggested by Nukiyama (1934). These regimes are shown in Figure 1. When the temperature of the heating surface is near the fluid saturation temperature, heat is transferred by convection currents to the free surface, where evaporation occurs (region I). Transition to nucleate boiling occurs when the surface temperature exceeds saturation by a few degrees (region II).

In **nucleate boiling** (region III), a thin layer of superheated liquid forms adjacent to the heating surface. In this layer, bubbles nucleate and grow from spots on the surface. The thermal resistance of the superheated liquid film is greatly reduced by bubble-induced agitation and vaporization. Increased wall temperature increases bubble population, causing a large increase in heat flux.

As heat flux or temperature difference increases further and as more vapor forms, liquid flow toward the surface is interrupted, and

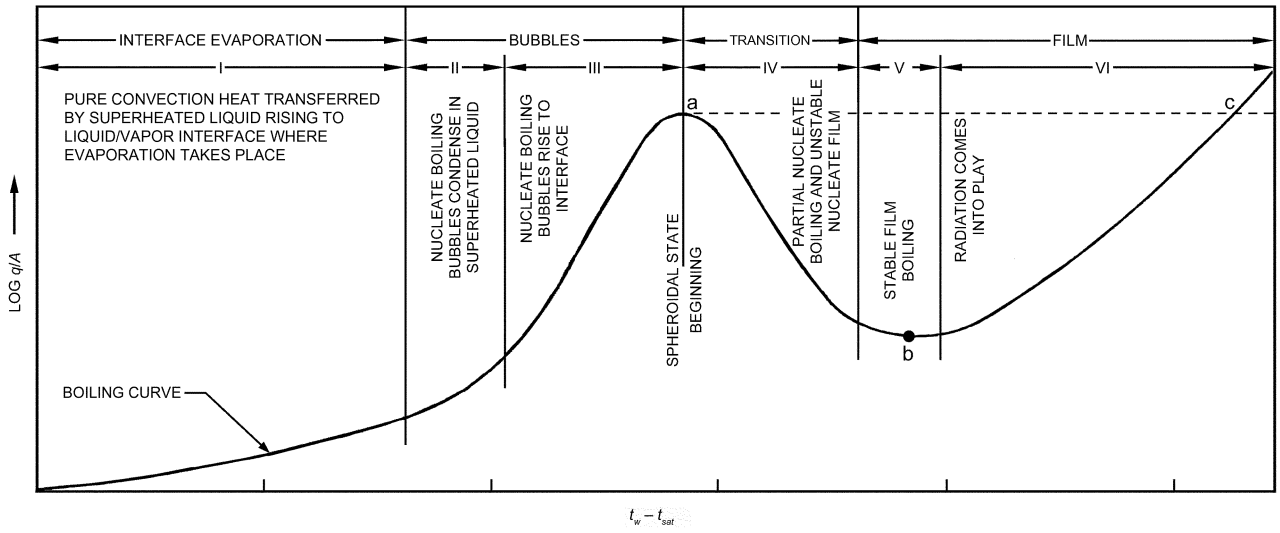

Fig. 1 Characteristic Pool Boiling Curve

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

a vapor blanket forms. This gives the **maximum heat flux**, which is at the **departure from nucleate boiling (DNB)** at point a in Figure 1. This flux is often called the **burnout heat flux** or **boiling crisis** because, for constant power-generating systems, an increase of heat flux beyond this point results in a jump of the heater temperature (to point c), often beyond the melting point of a metal heating surface.

In systems with controllable surface temperature, an increase beyond the temperature for DNB causes a decrease of heat flux density. This is the **transition boiling regime** (region IV); liquid alternately falls onto the surface and is repulsed by an explosive burst of vapor.

At sufficiently high surface temperatures, a stable vapor film forms at the heater surface; this is the **film boiling regime** (regions V and VI). Because heat transfer is by conduction (and some radiation) across the vapor film, the heater temperature is much higher than for comparable heat flux densities in the nucleate boiling regime. The **minimum film boiling (MFB)** heat flux (point b) is the lower end of the film boiling curve.

Free Surface Evaporation. In region I, where surface temperature exceeds liquid saturation temperature by less than a few degrees, no bubbles form. Evaporation occurs at the free surface by convection of superheated liquid from the heated surface. Correlations of heat transfer coefficients for this region are similar to those for fluids under ordinary natural convection [Equations (T1.1) to (T1.4)].

Nucleate Boiling. Much information is available on boiling heat transfer coefficients, but no universally reliable method is available for correlating the data. In the nucleate boiling regime, heat flux density is not a single valued function of the temperature but depends also on the nucleating characteristics of the surface, as shown by Figure 2 (Berenson 1962).

The equations proposed for correlating nucleate boiling data can be put in a form that relates heat transfer coefficient h to temperature difference $(t_s - t_{sat})$:

$$h = \text{constant}(t_s - t_{sat})^a \quad (1)$$

Exponent a is normally about 2 for a plain, smooth surface; its value depends on the thermodynamic and transport properties of the vapor and liquid. Nucleating characteristics of the surface, including the size distribution of surface cavities and wetting characteristics of the surface/liquid pair, affect the value of the multiplying constant and the value of a in Equation (1).

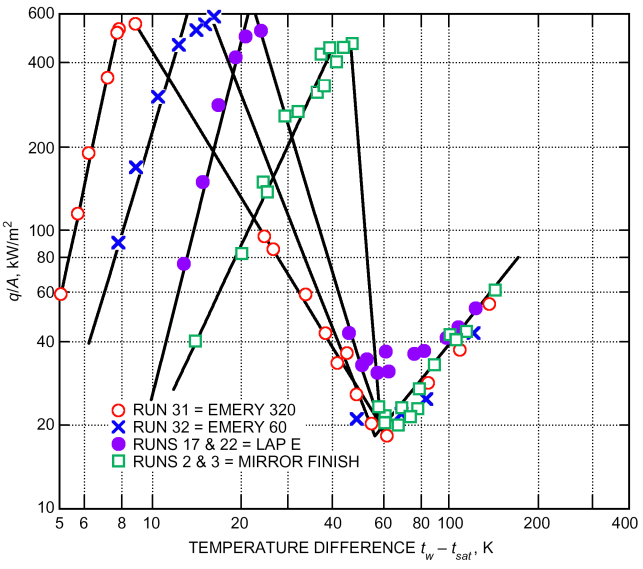

Fig. 2 Effect of Surface Roughness on Temperature in Pool Boiling of Pentane
(Berenson 1962)

In the following sections, correlations and nomographs for predicting nucleate and flow boiling of various refrigerants are given. For most cases, these correlations have been tested for refrigerants (e.g., R-11, R-12, R-113, R-114) that are now identified as environmentally harmful and are no longer used in new equipment. Thermal and fluid characteristics of alternative refrigerants/refrigerant mixtures have recently been extensively researched, and some correlations have been suggested.

Stephan and Abdelsalam (1980) developed a statistical approach for estimating heat transfer during nucleate boiling. The correlation [Equation (T1.5)] should be used with a fixed contact angle θ regardless of the fluid. Cooper (1984) proposed a dimensional correlation for nucleate boiling [Equation (T1.6)] based on analysis of a vast amount of data covering a wide range of parameters. The dimensions required are listed in Table 1. Based on inconclusive evidence, Cooper suggested a multiplier of 1.7 for copper surfaces, to be reevaluated as more data came forth. Most other researchers [e.g., Shah (2007)] have found the correlation gives better agreement without this multiplier, and thus do not recommend its use.

Gorenflo (1993) proposed a nucleate boiling correlation based on a set of reference conditions and a base heat transfer coefficient for each fluid, and provided base heat transfer coefficients for many fluids.

In addition to correlations dependent on thermodynamic and transport properties of the vapor and liquid, Borishansky et al. (1962), Lienhard and Schrock (1963), and Stephan (1992) documented a correlating method based on the law of corresponding states. The properties can be expressed in terms of fundamental molecular parameters, leading to scaling criteria based on reduced pressure $p_r = p/p_c$, where p_c is the critical thermodynamic pressure for the coolant. An example of this method of correlation is shown in Figure 3. Reference pressure p^* was chosen as $p^* = 0.029p_c$. This is a simple method for scaling the effect of pressure if data are available for one pressure level. It also is advantageous if the thermodynamic and particularly the transport properties used in several equations in Table 1 are not accurately known. In its present form, this correlation gives a value of $a = 2.33$ for the exponent in Equation (1) and consequently should apply for typical aged metal surfaces.

There are explicit heat transfer coefficient correlations based on the law of corresponding states for halogenated refrigerants (Danilova 1965), flooded evaporators (Starczewski 1965), and various other substances (Borishansky and Kosyrev 1966). Other investigations examined the effects of oil on boiling heat transfer from diverse configurations, including boiling from a flat plate (Stephan 1963), a 14.0 mm OD horizontal tube using an oil/R-12

Table 1 Equations for Natural Convection Boiling Heat Transfer

Description	References	Equations	
Free convection	Jakob (1949, 1957)	$\mathrm{Nu} = C(\mathrm{Gr})^m(\mathrm{Pr})^n$	(T1.1)
Free convection boiling, or boiling without bubbles for low Δt and $\mathrm{Gr\,Pr} < 10^8$. All properties based on liquid state.		Characteristic length scale for vertical surfaces is vertical height of plate or cylinder. For horizontal surfaces, $L_c = A_s/P$, where A_s is plate surface area and P is plate perimeter, is recommended. $\mathrm{Gr} = \frac{g\beta(t_s - t_{sat})L_c^3}{\nu^2}$	
Vertical submerged surface		$\mathrm{Nu} = 0.61(\mathrm{Gr})^{0.25}(\mathrm{Pr})^{0.25}$	(T1.2)
Horizontal submerged surface		$\mathrm{Nu} = 0.16(\mathrm{Gr})^{1/3}(\mathrm{Pr})^{1/3}$	(T1.3)
Simplified equation for water		$h \sim 17(\Delta t)^{1/3}$, where h is in W/(m²·K) and Δt is in K	(T1.4)
Nucleate boiling	Stephan and Abdelsalam (1980)	$\frac{hD_d}{k_l} = 0.0546\left[\left(\frac{\rho_v}{\rho_l}\right)^{0.5}\left(\frac{qD_d}{Ak_lt_{sat}}\right)\right]^{0.67}\left(\frac{h_{fg}D_d^2}{\alpha_l^2}\right)^{0.248}\left(\frac{\rho_l - \rho_v}{\rho_l}\right)^{-4.33}$ where $D_d = 0.0208\theta\left[\frac{\sigma}{g(\rho_l - \rho_v)}\right]^{0.5}$ with $\theta = 35°$.	(T1.5)
	Cooper (1984)	$h = 55p_r^{0.12 - 0.0912\ln(R_p)}(-0.4343\ln p_r)^{-0.55}M^{-0.5}\left(\frac{q}{A}\right)^{0.67}$ where h is in W/(m²·K), q/A is in W/m², and R_p is surface roughness in μm (if unknown, use 1 μm). Multiply h by 1.7 for copper surfaces (see text).	(T1.6)
Critical heat flux	Kutateladze (1951)	$\frac{q/A}{\rho_v h_{fg}}\left[\frac{\rho_v^2}{\sigma g(\rho_l - \rho_v)}\right]^{0.25} = K_D$	(T1.7)
	Zuber et al. (1962)	For many liquids, K_D varies from 0.12 to 0.16; an average value of 0.13 is recommended.	
Minimum heat flux in film boiling from horizontal plate	Zuber (1959)	$\frac{q}{A} = 0.09\rho_v h_{fg}\left[\frac{\sigma g(\rho_l - \rho_v)}{(\rho_l + \rho_v)^2}\right]^{1/4}$	(T1.8)
Minimum heat flux in film boiling from horizontal cylinders	Lienhard and Wong (1964)	$q/A = 0.633\left\{\frac{4B^2}{1 + B/2}\right\}^{0.25}\left\{0.09\rho_v h_{fg}\left[\frac{g\sigma(\rho_l - \rho_v)}{(\rho_l + \rho_v)^2}\right]^{0.25}\right\}$ where $B = (2L_b/D)^2$ and $L_b = \left[\frac{\sigma}{g(\rho_l - \rho_v)}\right]^{0.5}$	(T1.9)
Minimum temperature difference for film boiling from horizontal plate	Berenson (1961)	$(t_s - t_{sat}) = 0.127L_b\left(\frac{\rho_v h_{fg}}{k_v}\right)\left[\frac{g(\rho_l - \rho_v)}{\rho_l + \rho_v}\right]^{2/3}\left[\frac{\mu_v}{g(\rho_l - \rho_v)}\right]^{1/3}$	(T1.10)
Film boiling from horizontal plate	Berenson (1961)	$h = 0.425\left[\frac{k_v^3\rho_v h_{fg}g(\rho_l - \rho_v)}{\mu_v(t_s - t_{sat})L_b}\right]^{0.25}$	(T1.11)
Film boiling from horizontal cylinders	Bromley (1950)	$h = 0.62\left[\frac{k_v^3\rho_v h'_{fg}g(\rho_l - \rho_v)}{\mu_v(t_s - t_{sat})D}\right]^{0.25}$	(T1.12)
Effect of superheating	Anderson et al. (1966)	Substitute $h'_{fg} = h_{fg}\left(1 + 0.4c_{p,v}\frac{t_s - t_{sat}}{h_{fg}}\right)$	(T1.13)
Effect of radiation	Incropera and DeWitt (2002)	$h_t = h + \frac{3}{4}\frac{\varepsilon\sigma(t_s^4 - t_{sat}^4)}{t_s - t_{sat}}$	
Quenching spheres	Frederking and Clark (1962)	$\mathrm{Nu} = 0.15(\mathrm{Ra})^{1/3}$ for $\mathrm{Ra} > 5 \times 10^7$ $\mathrm{Ra} = \left[\frac{D^3g(\rho_l - \rho_v)}{\nu_v^2\rho_v}\mathrm{Pr}_v\left(\frac{h_{fg}}{c_{p,v}(t_s - t_{sat})} + 0.4\right)\frac{a}{g}\right]^{1/3}$ where a = local acceleration	(T1.14)

mixture (Tschernobyiski and Ratiani 1955), inside horizontal tubes using an oil/R-12 mixture (Breber et al. 1980; Green and Furse 1963; Worsoe-Schmidt 1959), and commercial copper tubing using R-11 and R-113 with oil content to 10% (Dougherty and Sauer 1974). Additionally, Furse (1965) examined R-11 and R-12 boiling over a flat horizontal copper surface.

Maximum Heat Flux and Film Boiling

Maximum, or critical, heat flux and the film boiling region are not as strongly affected by conditions of the heating surface as heat flux in the nucleate boiling region, making analysis of DNB and of film boiling more tractable.

Several mechanisms have been proposed for the onset of DNB [see Carey (1992) for a summary]. Each model is based on the scenario that a vapor blanket exists on portions of the heat transfer surface, greatly increasing thermal resistance. Zuber (1959) proposed that these blankets may result from Helmholtz instabilities in columns of vapor rising from the heated surface; another prominent theory supposes a macrolayer beneath the mushroom-shaped bubbles (Haramura and Katto 1983). In this case, DNB occurs when liquid beneath the bubbles is consumed before the bubbles depart and allow surrounding liquid to rewet the surface. Dhir and Liaw (1989) used a concept of bubble crowding proposed by Rohsenow and Griffith (1956) to produce a model that incorporates the effect of contact angle. Sefiane (2001) suggested that instabilities near the triple contact lines cause DNB. Fortunately, though significant disagreement remains about the mechanism of DNB, models using these differing conceptual approaches tend to lead to predictions within a factor of 2.

When DNB (point a in Figure 1) is assumed to be a hydrodynamic instability phenomenon, a simple relation [Equation (T1.7)] can be derived to predict this flux for pure, wetting liquids (Kutateladze 1951; Zuber et al. 1962). The dimensionless constant K varies from approximately 0.12 to 0.16 for a large variety of liquids. Kandlikar (2001) created a model for maximum heat flux explicitly incorporating the effects of contact angle and orientation. Equation (T1.7) compares favorably to Kandlikar's, and, because it is simpler, it is still recommended for general use. However, note that this equation is valid when the end effects are unimportant. Carey (1992) provides correlations to calculate maximum heat flux for various geometries based on this equation. Surface wettability, orientation, and roughness can affect DNB. For orientations other than upward facing, see Brusstar and Merte (1997) and Howard and Mudawar (1999). Liquid subcooling increases maximum heat flux; see Elkessabgi and Lienhard (1998) for subcooling's effects.

Van Stralen (1959) found that, for liquid mixtures, DNB is a function of concentration. As discussed by Stephan (1992), the maximum heat flux always lies between the values of the pure components. Unfortunately, the relationship of DNB to concentration is not simple, and several hypotheses [e.g., McGillis and Carey (1996); Reddy and Lienhard (1989); Van Stralen and Cole (1979)] have been put forward to explain the experimental data. For a more detailed overview of mixture boiling, refer to Thome and Shock (1984).

The minimum heat flux density (point b in Figure 1) in film boiling from a horizontal surface and a horizontal cylinder can be predicted by Equation (T1.8). The factor 0.09 was adjusted to fit experimental data; values predicted by the analysis were approximately 30% higher. The accuracy of Equation (T1.8) falls off rapidly with increasing p_r (Rohsenow et al. 1998). Berenson's (1961) Equations (T1.10) and (T1.11) predict the temperature difference at minimum heat flux and heat transfer coefficient for film boiling on a flat plate. The minimum heat flux for film boiling on a horizontal cylinder can be predicted by Equation (T1.9). As in Equation (T1.8), the factor 0.633 was adjusted to fit experimental data.

The heat transfer coefficient in film boiling from a horizontal surface can be predicted by Equation (T1.11), and from a horizontal cylinder by Equation (T1.12) (Bromley 1950).

Frederking and Clark (1962) found that, for turbulent film boiling, Equation (T1.13) agrees with data from experiments at reduced gravity (Jakob 1949, 1957; Kutateladze 1963; Rohsenow 1963; Westwater 1963).

Boiling/Evaporation in Tube Bundles

In **horizontal tube bundles**, flow may be gravity driven or pumped-assisted forced convection. In either case, subcooled liquid enters at the bottom. Sensible heat transfer and subcooled boiling occur until the liquid reaches saturation. Net vapor generation then starts, increasing velocity and thus convective heat transfer. Nucleate boiling also occurs if heat flux is high enough. Brisbane et al. (1980) proposed a computational model in which a liquid/vapor mixture moves up through the bundle, and vapor leaves at the top while liquid moves back down at the side of the bundle. Local heat transfer coefficients are calculated for each tube, considering local velocity, quality, and heat flux. To use this model, correlations for local heat transfer coefficients during subcooled and saturated boiling with flow across tubes are needed. Thome and Robinson (2004) presented a correlation that showed agreement with several data sets for saturated boiling on plain tube bundles. Shah (2005, 2007) gave general correlations for local heat transfer coefficients during subcooled boiling with cross flow, and for saturated boiling with cross flow. These are given in Table 2. Both these correlations agree with extensive databases that included all published data for single tubes and tubes inside bundles, including those correlated by Thome and Robinson (2004).

Data and design methods for bundles of finned and enhanced tubes were reviewed in Casciaro and Thome (2001), Collier and Thome (1996), and Thome (2010). Thome and Robinson (2004) carried out extensive tests on bundles of plain, finned, and enhanced tubes using three halocarbon refrigerants. The plain and finned-tube results correlated quite well with an asymptotic model combining convective and nucleate boiling (Robinson and Thome 2004a, 2004b). The results with enhanced tubes proved more difficult to explain. The correlation presented accounts for the effects of reduced pressure and local void fraction (Robinson and Thome 2004c; Thome and Robinson 2006). This data set was also used by Consolini et al. (2006) to develop models and correlations for local void fraction and pressure drop in flooded evaporator bundles.

Eckels and Gorgy (2012) and Gorgy and Eckels (2013) performed wide-ranging tests on bundles of enhanced tubes with various pitches and two refrigerants. They collected extensive data but did not attempt to test or develop any predictive method. Their data indicated that a pitch-to-diameter ratio of 1.33 was optimum.

Swain and Das (2014) performed a detailed review of literature on boiling in bundles with plain and enhanced tubes. The only well-verified correlation for plain tube bundles they identified was the Shah correlation (Table 2). For bundles of enhanced tubes, no well-verified correlation was identified. Hence, the best recourse for design is to use the data closest to the intended application.

Typical performance of vertical-tube natural circulation evaporators, based on data for water, is shown in Figure 4 (Perry 1950). Low coefficients are at low liquid levels because insufficient liquid covers the heating surface. The lower coefficient at high levels results from an adverse effect of hydrostatic head on temperature difference and circulation rate. Perry (1950) noted similar effects in horizontal shell-and-tube evaporators.

Forced-Convection Evaporation in Tubes

Flow Mechanics. When a mixture of liquid and vapor flows inside a tube, the flow pattern that develops depends on the mass fraction of liquid, fluid properties of each phase, and flow rate. In an evaporator tube, the mass fraction of liquid decreases along the circuit length, resulting in a series of changing vapor/liquid flow patterns. If the fluid enters as a subcooled liquid, the first indications of vapor generation are bubbles forming at the heated tube wall (nucleation). Subsequently, bubble, plug, churn (or semiannular), annular, spray annular, and mist flows can occur as vapor content

Table 2 Correlations for Local Heat Transfer Coefficients in Horizontal Tube Bundles

Description	References	Equations
Saturated boiling in plain tube bundles	Shah (2007)	For Bo $Fr_l^{0.3} > 0.0008$, $h_{TP} = h_{pb}$ (T2.1)
Verified range: water, pentane, halocarbons; single tubes and bundles, square in-line and triangular		For $0.00021 < Bo\ Fr_l^{0.3} < 0.0008$, $h_{TP} = \phi_0 h_{LT}$
Pitch/D 1.17 to 1.5		For Bo $Fr_l^{0.3} > 0.00021$, $h_{TP} = 2.3h_{LT}/(Z^{0.08}\ Fr_l^{0.22})$
D = 3.2 to 25.4 mm		$h_{LT}D/k_f = 0.21(GD/\mu_f)^{0.62}\ Pr_f^{0.4}$
p_r = 0.005 to 0.19		ϕ_0 is the larger of that given by the following two equations:
G = 1.3 to 1391 kg/(m^2·s)		$\phi_0 = 443\ Bo^{0.65}$
Re_l = 58 to 4 949 462		$\phi_0 = 31\ Bo^{0.33}$
Bo × 10^4 = 0.12 to 2632		h_{pb} by Cooper correlation without multiplier for copper surface, G based on narrowest gap between tubes.
Data from 18 sources		$Fr_l = G^2/(\rho_f^2 gD)$ $Z = (1/x - 1)^{0.8} p_r^{0.4}$
		All properties at saturation temperature
Subcooled boiling	Shah (2005)	Low subcooling regime, $h_{TP} = \phi_0 h_{LT}$ (T2.2)
Verified range: water and halocarbons; single tubes and tube bundles		High subcooling regime, $h_{TP} = q/\Delta t_{sat} = (\phi_0 + \Delta t_{sc}/\Delta t_{sat})h_{LT}$
D = 1.2 to 26.4 mm		ϕ_0 as for saturated boiling
p_r = 0.005 to 0.15		High subcooling regime when
Subcooling Δt_{sc} = 0 to 93 K		$q/(GC_{pf}\Delta t_{sc}) > 38(GDC_{pf}/\mu_f)$ or when $Bo < 2.56 \times 10^{-4}$
Re_l = 67 to 260 464		$\Delta t_{sat} = t_w - t_{sat}$
Bo × 10^4 = 0.6 to 1100		All properties at bulk liquid temperature
Data from 29 sources		

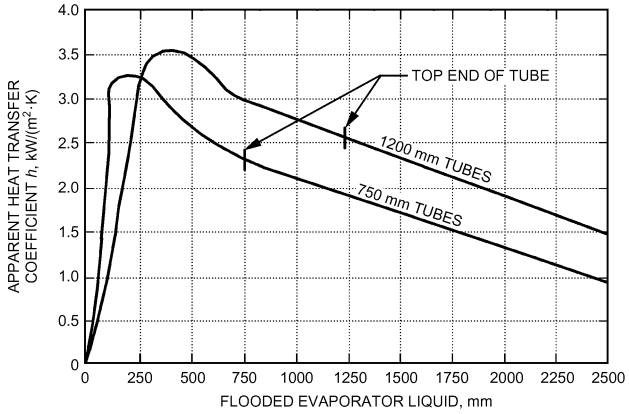

Fig. 4 Boiling Heat Transfer Coefficients for Flooded Evaporator
(Perry 1950)

increases for two-phase flows in horizontal tubes. Idealized flow patterns are shown in Figure 5A for a horizontal tube evaporator. Note that there is currently no general agreement on the names of two-phase flow patterns, and the same name may mean different patterns in vertical, horizontal, and small-tube flow. For detailed delineation of flow patterns, see Barnea and Taitel (1986) or Spedding and Spence (1993) for tubes and pipes between 3 and 75 mm in diameter, Coleman and Garimella (1999) for tubes less than 3 mm in diameter, and Thome (2001) for flow regime definitions useful in modeling heat transfer.

Increased computing power has allowed greater emphasis on flow-pattern-specific heat transfer and pressure drop models (although there is not uniform agreement among researchers and practitioners that this is always appropriate). Virtually all of the over 1000 articles on two-phase flow patterns and transitions have studied air/water or air/oil flows. Dobson and Chato (1998) found that the Mandhane et al. (1974) flow map, adjusted for the properties of refrigerants, produced satisfactory agreement with their observations in horizontal condensation. Thome (2003) summarized efforts to generate diabatic flow pattern maps in both evaporation and condensation for a number of refrigerants.

The concepts of vapor quality and void fraction are frequently used in two-phase flow models. **Vapor quality** x is the ratio of mass (or mass flow rate) of vapor to total mass (or mass flow rate) of the mixture. The usual flowing vapor quality or vapor fraction is referred to throughout this discussion. Static vapor quality is smaller because vapor in the core flows at a higher average velocity than liquid at the walls. In addition, it is very important to recognize that vapor quality as defined here is frequently not equal to the thermodynamic equilibrium quality, because of significant temperature and velocity gradients in a diabatic flowing vapor/liquid mixture. Some models use the thermodynamic equilibrium quality, and, as a result, require negative values in the subcooled boiling region and values greater than unity in the post-dryout or mist flow region. This is discussed further in Hetsroni (1986).

The **area void fraction**, or just **void fraction**, ε_v is the ratio of the tube cross section filled with vapor to the total cross-sectional area. Vapor quality and area void fraction are related by definition:

$$\frac{x}{1-x} = \frac{\rho_v}{\rho_l} \times \frac{V_v}{V_l} \times \frac{\varepsilon_v}{1-\varepsilon_v} \tag{2}$$

The ratio of velocities V_v/V_l in Equation (2) is called the **slip ratio**. Note that the static void fraction and the flowing void fraction at a given vapor quality differ by a factor equal to the slip ratio.

Because nucleation occurs at the heated surface in a thin sublayer of superheated liquid, boiling in forced convection may begin while the bulk of the liquid is subcooled. Depending on the nature of the fluid and amount of subcooling, bubbles can either collapse or continue to grow and coalesce (Figure 5A), as Gouse and Coumou (1965) observed for R-113. Bergles and Rohsenow (1964) developed a method to determine the point of incipient surface boiling.

Licensed for single user. © 2021 ASHRAE, Inc.

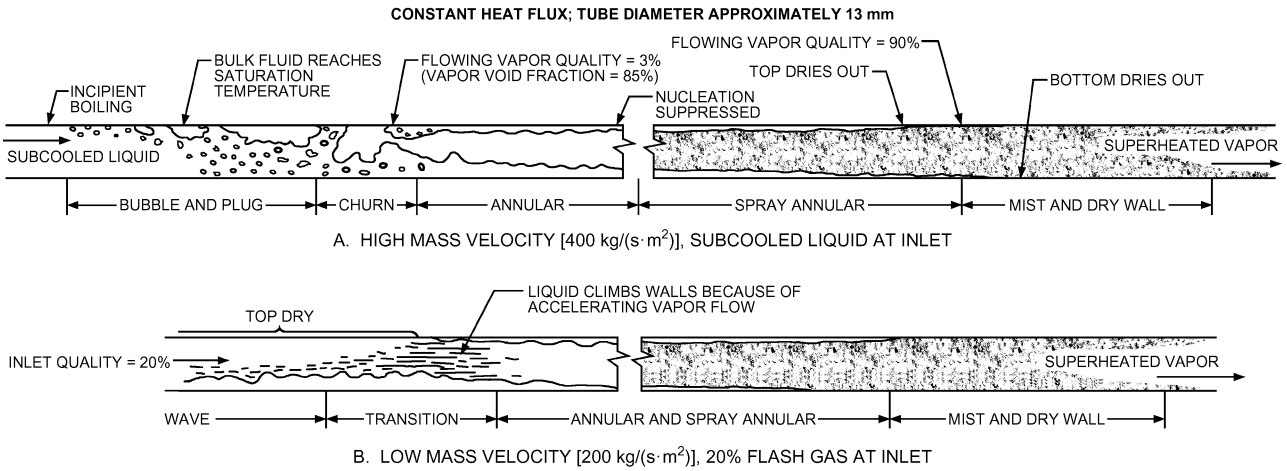

Fig. 5 Flow Regimes in Typical Smooth Horizontal Tube Evaporator

After nucleation begins, bubbles quickly agglomerate to form vapor plugs at the center of a vertical tube, or, as shown in Figure 5A, along the top surface of a horizontal tube. At the point where the bulk of the fluid reaches saturation temperature, which corresponds to local static pressure, there will be up to 1% vapor quality (and a negative thermodynamic equilibrium quality) because of the preceding surface boiling (Guerrieri and Talty 1956).

Further coalescence of vapor bubbles and plugs results in churn, or semiannular flow. If fluid velocity is high enough, a continuous vapor core surrounded by a liquid annulus at the tube wall soon forms. This occurs when the void fraction is approximately 85%; with common refrigerants, this equals a vapor quality of about 10 to 30%.

If two-phase mass velocity is high [greater than 200 kg/(s·m^2) for a 12 mm tube], annular flow with small drops of entrained liquid in the vapor core (spray) can persist over a vapor quality range from about 10% to more than 90%. Refrigerant evaporators are fed from an expansion device at vapor qualities of approximately 20%, so that annular and spray annular flow predominate in most tube lengths. In a vertical tube, the liquid annulus is distributed uniformly over the periphery, but it is somewhat asymmetric in a horizontal tube (Figure 5A). As vapor quality reaches about 80% (the actual quality varies from about 70 to 90%, depending on tube diameter, mass velocity, refrigerant, and wall enhancement), portions of the surface dry out. In a horizontal tube, dryout occurs first at the top of the tube and progresses toward the bottom with increasing vapor quality (Figure 5A). Kattan et al. (1998a, 1998b) indicated a very sharp decrease in the local heat transfer coefficient as well as the pressure drop at this point.

If two-phase mass velocity is low [less than 200 kg/(s·m^2) for a 12 mm horizontal tube], liquid occupies only the lower cross section of the tube. This causes a wavy type of flow at vapor qualities above about 5%. As the vapor accelerates with increasing evaporation, the interface is disturbed sufficiently to develop annular flow (Figure 5B). Liquid slugging can be superimposed on the flow configurations shown; the liquid forms a continuous, or nearly continuous, sheet over the tube cross section, and the slugs move rapidly and at irregular intervals. Kattan et al. (1998a) presented a general method for predicting flow pattern transitions (i.e., a flow pattern map) based on observations for R-134a, R-125, R-502, R-402A, R-404A, R-407C, and ammonia.

Heat Transfer. In direct-exchange (DX) evaporators, a saturated mixture of liquid and flash gas enters the evaporator. In evaporators with forced or gravity recirculation, liquid is subcooled at the entrance. Subcooled boiling usually occurs until the liquid reaches saturation. Several well-verified correlations for subcooled boiling are available [e.g., Chen (1966), Gungor and Winterton (1986), Kandlikar (1990), Li and Wu (2010a), Liu and Winterton (1991), Shah (1977, 1983)]. The last mentioned is the most verified and is given in Table 3. Note that the subcooling regime can alternatively be determined by Saha and Zuber's (1974) model, which is explicit.

For **saturated boiling**, Figure 6 gives heat transfer data for R-22 evaporating in a 19.6 mm tube (Gouse and Coumou 1965). At low mass velocities [below 200 kg/(s·m^2)], the wavy flow regime shown in Figure 5B probably exists, and the heat transfer coefficient is nearly constant along the tube length, dropping at the exit as complete vaporization occurs. At higher mass velocities, flow is usually annular, and the coefficient increases as the vapor accelerates. As the surface dries and flow reaches between 70 and 90% vapor quality, the coefficient drops sharply.

Heat transfer coefficients depend on the contributions of nucleate boiling and forced convection. Many correlations have been proposed for calculating heat transfer coefficients during saturated boiling. Some of them use the boiling number Bo to estimate nucleate boiling contribution, whereas others use pool boiling correlations. Shah (2006) compared several correlations against a wide range of data that included 30 pure fluids. Best results were found with the correlations of Shah (1982) and Gungor and Winterton (1987), the mean deviation for all data being about 17%. Both of these use the boiling number and are given in Table 3. These are applicable to all flow patterns and to horizontal and vertical tubes. Other correlations tested included Chen (1963), Kandlikar (1990), Liu and Winterton (1991), and Steiner and Taborek (1992); their performance was much inferior. Another well-validated correlation is that of Gungor and Winterton (1986), which uses a pool boiling correlation for nucleate boiling contribution. The flow-pattern-based model described by Thome (2001) includes specific models for each flow pattern type and has been tested with newer refrigerants such as R-134a and R-407C.

Recently, there has been great interest in using **carbon dioxide** as a refrigerant, and many experimental studies on its heat transfer have proposed correlations specifically for CO_2. Shah (2014a) evaluated 11 general and CO_2-specific correlations against 1052 data points from 41 data sets from 32 studies; tube diameters ranged from 0.51 to 14 mm, and pressures and flow rates varied widely. Over all tube diameters, the Liu and Winterton (1991) correlation performed best, with a mean absolute deviation of 26.1%. The Shah correlation (Table 3) also gave good agreement by using $\phi_0 = 1820\ Bo^{0.68}$, with a deviation of 26.8%. For channels with diameters

Table 3 Equations for Forced Convection Boiling in Tubes

Description	References	Equations
Horizontal and vertical tubes and annuli, saturated boiling Compiled from a database of over 3600 data points, including data for R-11, R-12, R-22, R-113, R-114, and water. Applicable to vertical flows and horizontal tubes.	Gungor and Winterton (1987)	$h = E(h_{nb} + h_{cb})$ (T3.1) where $h_{cb} = 1.12\left[\frac{x}{(1-x)}\right]^{0.75}\left(\frac{\rho_f}{\rho_g}\right)^{0.41} h_f$ $h_{nb} = (1 + 3000\ \mathrm{Bo}^{0.86})h_f$ $h_f = 0.023\ \mathrm{Re}_l^{0.8}\mathrm{Pr}_l^{0.4}(k_l/D)$ $\mathrm{Re}_l = \frac{G(1-x)D}{\mu_l}, \quad \mathrm{Bo} = \frac{q''}{Gh_{fg}}$ For horizontal tubes with $\mathrm{Fr}_l > 0.05$ and for vertical tubes, $E = 1$. For horizontal tube with $\mathrm{Fr}_l < 0.05$, $E = \mathrm{Fr}_l^{(0.1-2\ \mathrm{Fr}_l)}$ $\mathrm{Fr}_l = \frac{G^2}{\rho_l^2 Dg}$ For annuli, equivalent diameter based on heated perimeter.
Verified range: D = 1.1 to 27.1 mm p_r = 0.0053 to 0.78 Bo × 10^4 = 0.22 to 74.2 G = 10 to 11 000 kg/(m²·s) 30 fluids (water, halocarbons, cryogens, chemicals)	Shah (1982)	Boiling heat transfer coefficient h is the largest of that given by the following equations: $h = \phi_0 h_f$ (T3.2a) where $\phi_0 = 230\ \mathrm{Bo}^{0.5}$ h_f in Equation (T3.2a) is calculated at $x = 0$. In the following equations, it is at the actual x. $h = 1.8[\mathrm{Co}(0.38\ \mathrm{Fr}_l^{-0.3})^n]^{-0.8} h_f$ (T3.2b) $h = F\phi_0 \exp\{2.47[\mathrm{Co}(0.38\ \mathrm{Fr}_l^{-0.3})^n]^{-0.15}\} h_f$ $h = F\phi_0 \exp\{2.74[\mathrm{Co}(0.38\ \mathrm{Fr}_l^{-0.3})^n]^{-0.1}\} h_f$ where h_f and Fr_l are calculated the same way as for Gungor and Winterton correlation $F = 0.064$ if Bo > 0.0011 $F = 0.067$ if Bo < 0.0011 *Vertical*: $n = 0$ *Horizontal*: $n = 0$ if $\mathrm{Fr}_l > 0.04$ $n = 1$ for $\mathrm{Fr}_l \le 0.04$ $\mathrm{Co} = \left(\frac{1-x}{x}\right)^{0.8}\left(\frac{\rho_v}{\rho_l}\right)^{0.5}$ For annuli, equivalent diameter based on heated perimeter when gap < 4 mm and on wetted perimeter when gap > 4 mm.
Subcooled boiling in horizontal and vertical tubes and annuli Tubes: 2.4 to 27.1 dia. Annuli: gaps 1 to 6.4 mm, internal, external, and two-sided heating Fluids: water, ammonia, halocarbons, organics Tube materials: copper, SS, glass, nickel, Inconel Reduced pressure: 0.005 to 0.89 ΔT_{sc}: 0 to 153 K G: 200 to 87,000 kg/(m²·s) Re_l: 1400 to 360,000 Bo × 10^4: 0.1 to 54	Shah (1977, 1983)	Low-subcooling regime: $h = q/\Delta t_{sat} = 230\ \mathrm{Bo}^{0.5} h_f$ (T3.3a) High-subcooling regime: $h = q/\Delta t_{sat} = (230\ \mathrm{Bo}^{0.5} + \Delta t_{sc}/\Delta t_{sat}) h_f$ (T3.3b) All properties at bulk fluid temperature. High-subcooling regime occurs when $(\Delta t_{sc}/\Delta t_{sat}) > 2$ or $> 0.00063\ \mathrm{Bo}^{1.25}$ (T3.3c) h_f as above with $x = 0$. For annuli, equivalent diameter based on heated perimeter when gap < 4 mm and on wetted perimeter when gap > 4 mm All properties at bulk liquid temperature except latent heat at saturation temperature.

Table 3 Equations for Forced Convection Boiling in Tubes (*Continued*)

Description	References	Equations
Saturated boiling in round and rectangular channels Compiled from a database of over 3744 data points, including data for R-123, R-236fa, ethanol, CO_2, water, and R-134a. D_h = 0.19 to 2.01 mm G: 23.4 to 1500 kg/(m²·s) q: 3 to 715 kW/m² P_r (reduced pressure): 0.023-0.61 x (mass quality): $0 < x < x_{CHF}$ (mass quality at critical heat flux)	Li and Wu (2010a)	$h = 334\text{Bl}^{0.3}(\text{BoRe}_f^{0.36})^{0.4}(k_f/d_h)$ (T3.4) $\text{Bl} = q'_w/(Gh_{fg})$ $\text{Bo} = \frac{g(\rho_l - \rho_g)d_h^2}{\sigma}$

Note: All equations are dimensionless.

< 3 mm, the correlation of Yoon et al. (2004) was best, with a mean absolute deviation of 18.7%; the Li and Wu (2010a) correlation for minichannels had a deviation of 20.3%. Data from different studies often do not agree with one another in the same range of parameters, which suggests that some data might be erroneous.

Boiling Mixtures. Most recently developed refrigerants and those in development are mixtures of two or more fluids. Heat transfer coefficients of zeotropic mixtures are lower than those of their pure components because of mass transfer resistance, and the difference grows with increasing glide (i.e., the difference between the mixture's dew point and bubble point temperatures). Hence, the formulas presented previously may be directly used only if the glide is small (e.g., up to 1 K). Many calculation methods [e.g., Thome (1996)] for mixtures have been proposed in which a correction factor is applied only to the nucleate boiling terms of correlations for pure fluids. Shah (2015a) noted that mass transfer resistance also occurs during convective boiling (boiling without nucleation), so correction is also needed in this region for both nucleate boiling and convective boiling contributions. For the nucleate boiling region, the following correction factor of Thome and Shakir (1987) for pool boiling of mixtures is used:

$$F_{TS} = \left\{1 + \left(\frac{h_I}{q}\right)(t_{dew} - t_{bub})\left[1 - \exp\left(\frac{-Bq}{\rho_f h_{lg} \beta_f}\right)\right]\right\}^{-1} \quad (3)$$

where h_I is the ideal heat transfer coefficient calculated by a pool boiling correlation for pure fluids using mixture properties, B is the scaling factor (assumed to be 1: all heat transferred to bubble interface is converted to latent heat), and β_f is the liquid-phase mass transfer coefficient, which is recommended to be constant at 0.0003 m/s. For the convective boiling contribution, Shah used the Bell and Ghaly (1973) correction factor for condensation heat transfer, which is given in Equation (19). For boiling, t_{dew} is replaced by the bubble point temperature t_{bub}, and h_c is replaced by the boiling heat transfer coefficient. Using this method, the Gungor and Winterton correlation in Table 3 may be written for mixtures as

$$h_{mix} = E\left[F_{TS} h_{nb} + \left(\frac{1}{h_{cb}} + \frac{Y}{h_{GS}}\right)^{-1}\right] \quad (4)$$

Other pure-fluid correlations can be similarly modified for mixtures. Shah (2015a) evaluated this method by applying it to five correlations for pure fluids and comparing them to a database for 45 mixtures of 19 fluids from 21 independent studies. The mixtures had two to six components. The data included tube diameters of 0.19 to 14 mm, horizontal and vertical orientations, flow rates 50 to 930 kg/(m²·s), reduced pressures from 0.05 to 0.63, and temperature glides up to 156 K. The Cooper correlation was used to calculate h_I in the Thome-Shakir correction factor F_{TS}. Good agreement of this method was found using the correlations of Shah (1982), Gungor and Winterton (1987), and Liu and Winterton (1991). The exception was the only data set for LNG (liquefied natural gas) which agreed with the Shah (1982) and Gungor-Winterton (1987) correlations without any correction. This is the only well-verified method available and is therefore recommended.

Mini- and Microchannels. Some correlations for conventional or macro/minichannels have been found not suitable for microchannels. Numerous definitions have been offered by the various investigators to define microchannels; most use hydraulic diameter as a criterion, though in some cases this may not be the best way to distinguish the phenomenon in microchannels from that in conventional (mini- or macro-) channels. Two widely known criteria are from

- Mehendale et al. (2000), who used hydraulic diameter to classify micro heat exchangers as follows:
  - Micro heat exchanger: 1 μm ≤ d_h ≤ 100 μm
  - Meso heat exchanger: 100 μm ≤ d_h ≤ 1 mm
  - Compact heat exchanger: 1 mm ≤ d_h ≤ 6 mm
  - Conventional heat exchanger: d_h > 6 mm
- Kandlikar and Grande (2003), who classified single- and two-phase microchannels as follows:
  - Conventional channels: d_h > 3 mm
  - Minichannels: 3 mm ≥ d_h > 200 μm
  - Microchannels: 200 μm ≥ d_h > 10 μm

Kandlikar and Grande's definition appears to be the most accepted by the technical community. Most recent experimental and modeling studies suggest that the phenomenon in channels larger than 200 μm appears to be more or less same as that in mini- and macrochannels, thus further supporting this definition for microchannels. Numerous attempts have been made to develop correlations for such channels, but most of those published were validated with only one or two data sets. Correlations from Li and Wu (2010a, 2010b) and Sun and Mishima (2009) show reasonable agreement with varied data from many sources; Li and Wu's is the most verified and has a clearly defined application range (see Table 3). Li and Wu (2010a) and Yen et al. (2003) showed that correlations by Chen (1966), Gungor and Winterton (1986), and Kandlikar (1990) over- or underpredict experimental data of microchannels. Chen's and Kandlikar's correlations underpredicted Yen et al.'s (2003) experimental data by more than an order of magnitude. In addition, Gungor and Winterton's correlation overpredicted the experimental data

Licensed for single user. © 2021 ASHRAE, Inc.

Licensed for single user. © 2021 ASHRAE, Inc.

for channels with hydraulic diameters of 0.586 and 0.19 mm, although the correlation was well matched with data for the 2.01 mm channel. However, Li and Wu's correlation predicted the experimental data well for the range of hydraulic diameters from 0.19 mm to 2.01 mm within the ±30% band. Shah's correlation was not considered in this study, but is expected also to underpredict experimental results for microchannels, because of its fundamental similarity to Chen's correlation. Additional information about microchannels, their various classification, single-phase and phase-change heat transfer and pressure drop correlations, and their future or emerging applications can be found in Ohadi et al. (2013).

Critical Heat Flux (CHF). The preceding correlations are applicable before occurrence of dryout or critical heat flux. After that, transition boiling and film boiling occur. Hall and Mudawar (2000a, 2000b) extensively review CHF data and correlations for flow boiling in tubes.

Shah (1980a, 2016a) gave a graphical and mathematical correlation for CHF during upflow in vertical annuli. This correlation was validated with data from 58 data sets from 25 studies, including annuli with internal, external, and bilateral heating; 10 fluids, including water and refrigerants; reduced pressures from 0.016 to 0.905; flow rates from 100 to 15 759 kg/(m^2·s); tube diameters from 1.5 to 96.5 mm; annular gaps from 0.3 to 16.5 mm; ratios of length to heated equivalent diameter from 1.3 to 394; inlet qualities from –3.3 to +0.91; and critical qualities from –2.7 to +0.95. All data points were predicted with a mean absolute deviation of 16.5%. No other well-verified general correlation for annuli is available.

For upflow in vertical tubes, Shah (1979a, 1987) also gave a general graphical and mathematical correlation for CHF. Shah (2016b) further evaluated its applicability to mini/microchannels. In all, it was validated with data for single tubes and multichannels of equivalent diameters from 0.13 to 37.8 mm, reduced pressures from 0.0014 to 0.96, flow rates from 10 to 41 810 kg/(m^2·s), and qualities from –4 to +1.0. The data included 34 diverse fluids (water, liquid metals, new and old halocarbon refrigerants, hydrocarbons, and cryogens). The same data were also compared to other correlations, and the Shah correlation was found significantly more accurate. For mini/micro channels ($D \le 3$ mm), Shah's and Katto and Ohno's (1984) correlations gave mean absolute deviations of 18.9 and 33.2%, respectively.

Most evaporators used in air conditioning and refrigeration are horizontal and have nonuniform heat flux, so predicting CHF in horizontal channels is of great importance. The following correlation provides K_{hor}, the ratio of CHF in horizontal channels to CHF in vertical upflow at identical conditions (Shah 2015b):

$$\text{For } x_{in} < 0 \text{ when } L/D < 10$$
$$K_{hor} = 1 \tag{5}$$

$$\text{For } x_c \le 0.05$$
$$K_{hor} = 0.725\ \mathrm{Fr}_l^{0.082} \le 1 \tag{6}$$

$$\text{For } x_c > 0.05$$
$$K_{hor} = 0.64\ \mathrm{Fr}_{TP}^{0.15} \le 1 \tag{7}$$

Thus, if K_{hor} calculated with Equation (6) or (7) is greater than 1, use $K_{hor} = 1$. According to Equation (6), $K_{hor} = 1$ at $\mathrm{Fr}_l \ge 50$. According to Equation (7), $K_{hor} = 1$ at $\mathrm{Fr}_{TP} \ge 20$.

$$K_{hor} = q_{c,hor}/q_{c,ver}$$

where $q_{c,hor}$ and $q_{c,ver}$ are the CHF in horizontal and vertical upflow, respectively.

$$\mathrm{Fr}_l = G^2/(\rho_l^2 gD) \quad \text{and} \quad \mathrm{Fr}_{TP} = x_c G/[gD\rho_g(\rho_l - \rho_g)]^{0.5}$$

where x_c is the critical quality and x_{in} is the inlet quality.

For channels with nonuniform heat flux, critical heat flux is the total heat applied over the channel surface up to CHF point divided by the surface area up to that point. For noncircular channels and for channels heated on only part of their circumference, use equivalent diameter based on heated perimeter. This correlation was compared to a database that included 10 fluids (water, refrigerants, and hydrocarbons) in single and multiple channels of diameters 0.13 to 24.3 mm, reduced pressures from 0.005 to 0.9, mass flux from 20 to 11 390 kg/(m^2·s), inlet qualities from –1.05 to 0.72, and critical qualities from –0.2 to 0.99. Data included uniform and nonuniform heat flux. With CHF for vertical channels calculated by the Shah (1987) correlation, it predicted 878 data points from 39 data sets from 18 sources, with a mean absolute deviation of 15.4%. The same data were also compared to six other correlations, but none gave good agreement.

Post-CHF Heat Transfer. After CHF, transition boiling and film boiling occur. Film boiling can be the inverted annular type or the dispersed flow type. The former occurs only for a short length, if at all. For dispersed film boiling, the most verified general correlation is by Shah (1980b) in graphical form (Figure 7), converted to equation form by Shah and Siddiqui (2000). Fr_l is same as in Table 3. It is based on the two-step physical model and validated with wide-ranging data that included cryogens, refrigerants, and organics. At the dryout point, the actual quality x_A equals equilibrium quality x_E. At larger Bo, calculate x_A from Figure 7 as follows:

1. Locate x_c on the equilibrium line.
2. If x_c is below the intersection with Fr_l curve, read x_A along this line till it intersects the Fr_l curve and then read along that curve.
3. If x_c is above the intersection with Fr_l curve, draw a tangent to the curve; x_A is then read along the tangent up to the intersection point and then along the Fr_l curve.
4. Then calculate the actual enthalpy of vapor H_g by Equation (8):

$$(x_E - x_A)/x_A h_{fg} = H_g - H_{g,sat} \tag{8}$$

For Bo < 0.0005, calculate $(x_E - x_A)$ in the same way, then multiply it by (Bo/0.0005).

$H_{g,sat}$ is the enthalpy of saturated vapor. Knowing H_g, actual vapor temperature t_g is known. Vapor-phase heat transfer coefficient is calculated by Equations (9a) and (9b) using properties at actual vapor temperature (except for water, for which film temperature is used):

For $\mathrm{Re} < 10^4$

$$h_g D/k_g = 0.023(GDx_A/\mu_g\alpha)^{0.8}\ \mathrm{Pr}_g^{0.4} \tag{9a}$$

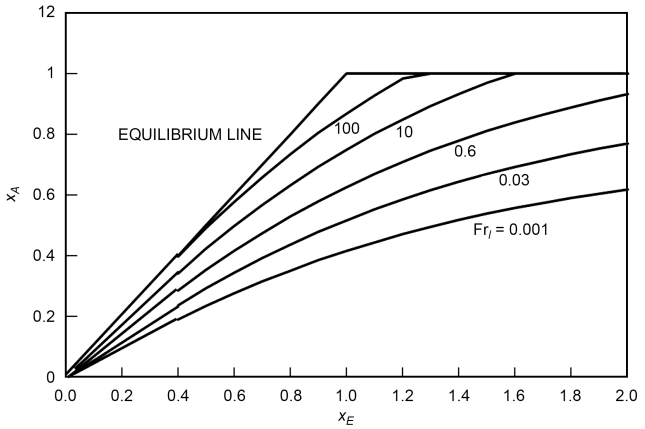

Fig. 7 Film Boiling Correlation
(Shah and Siddiqui 2000)

For $Re > 10^4$

$$h_g D/k_g = 0.00834(GDx_A/\mu_g\alpha)^{0.8774}\,Pr_g^{0.6112} \quad (9b)$$

The wall temperature t_w at heat flux q is then obtained by

$$q = h_g F_{dc}(t_w - t_g) \quad (10)$$

F_{dc} is the droplet cooling factor, which is 1 except when $p_r > 0.8$ and $L/D > 30$, in which case

$$F_{dc} = 2.64p_r - 1.11 \quad (11)$$

Void fraction α is calculated by the homogeneous model, which gives

$$\alpha = \frac{x_A\rho_f}{(1-x_A)\rho_g + \rho_f x_A} \quad (12)$$

Fr_l is defined in Table 3. The critical quality x_c is calculated by a suitable method as described in the foregoing. For horizontal tubes, wall temperatures at top and bottom are calculated as above using the x_c at that location.

Calculations for calculating x_A by equations are described now. The curves in the figure are represented by the following equations:

For $x_E \geq 0.4$,

$$x_A = (A_1 + A_2x_E + A_3x_E^2 + A_4x_E^3)Fr_l^{0.064} \quad (13)$$

$$A_1 = -0.0347,\ A_2 = 0.9335,\ A_3 = -0.2875,\ A_4 = 0.035$$

x_A from Equation (13) is corrected as: If $x_A > x_E$, then $x_A = x_E$. If $x_A > 1$, then $x_A = 1$.

For $x_E < 0.4$, the correlating curves in Figure 7 are represented by lines joining x_A at $x_E = 0.4$ from Equation (13) and intersecting the equilibrium line ($x_A = x_E$) at

$$x_{A,INT} = x_{E,INT} = 0.19\,Fr_l^{0.16} \quad (14)$$

Calculation is as follows:

1. For $x_c \leq x_{E,INT}$, $x_A = x_E$ for $x_E \leq x_{E,INT}$. For $x_E > x_{E,INT}$, obtain x_A from Equations (13) and (14).
2. For $x_c > x_{E,INT}$, determine the point where tangent from $x_E = x_A = x_c$ touches the curve of Equation (11). The point of tangency is at the intersection of Equations (13) and (15), obtained by simultaneous solution of the two equations.

$$x_A = x_c + (x_E - x_c)(A_2 + 2A_3x_E + 3A_4x_E^2)\,Fr_l^{0.064} \quad (15)$$

For $x_E < x_E$ at the tangent point, x_A is obtained from the straight line joining the tangent point to x_c at the equilibrium line. Beyond the tangent point, it is given by Equation (12).

This correlation was verified with data for vertical and horizontal tubes of diameters 1.1 to 24.3 mm, many fluids (e.g., water, halocarbons, cryogens, methane, propane), and pressures of 100 to 25 000 kPa. Petterson (2004) found good agreement of this correlation with data for CO_2 in a minichannel. Ayad et al. (2012) reported satisfactory agreement with data for CO_2 from several sources.

Effect of Lubricants. The effect of lubricant on evaporation heat transfer coefficients has been studied by many authors. Eckels et al. (1994) and Schlager et al. (1987) showed that the average heat transfer coefficients during evaporation of R-22 and R-134a in smooth and enhanced tubes decrease in the presence of lubricant (up to a 20% reduction at 5% lubricant concentration by mass). Slight enhancements at lubricant concentrations under 3% are observed with some refrigerant lubricant mixtures. Zeurcher et al. (1998) studied local heat transfer coefficients of refrigerant/lubricant mixtures in the dry-wall region of the evaporator (see Figure 5) and proposed prediction methods. The effect of lubricant concentration on local heat transfer coefficients was shown to depend on mass flux and vapor quality. At low mass fluxes [less than about 200 kg/(m^2·s)], oil sharply decreased performance, whereas at higher mass fluxes [greater than 200 kg/(m^2·s)], enhancements at vapor qualities in the range of 0.35 to 0.7 were seen. The foregoing information is for miscible oil/refrigerant mixtures. Shah (1975) found that miscible oil in ammonia evaporators forms thin films around the tube perimeter, drastically reducing the heat transfer coefficients. The thickness of oil film δ to account for the reduction in heat transfer during single-phase flow was given by

$$\delta/D = 0.028/Re_{LT}^{0.23} \quad (16)$$

where Re_{LT} is the Reynolds number with all mass flowing in liquid form. Shah's (1976) correlation for boiling gave reasonable agreement with ammonia data when the resistance of the calculated oil film was taken into account. Chaddock and Buzzard (1986) also reported reduction of heat transfer because of oil films in an ammonia evaporator with immiscible oil. Similar results may be expected with other immiscible refrigerant/oil mixtures.

Boiling in Plate Heat Exchangers (PHEs)

For a description of plate heat exchanger geometry, see the Plate Heat Exchangers section of Chapter 4.

Little information is available on two-phase flow in plate exchangers; for brief discussions, see Hesselgreaves (1990), Jonsson (1985), Kumar (1984), Panchal (1985, 1990), Panchal and Hillis (1984), Panchal et al. (1983), Syed (1990), Thonon (1995), Thonon et al. (1995), and Young (1994).

General correlations for evaporators and condensers should be similar to those for circular and noncircular conduits, with specific constants or variables defining plate geometry. Correlations for flooded evaporators differ somewhat from those for a typical flooded shell-and-tube, where the bulk of heat transfer results mainly from pool boiling. Because of the narrow, complex passages in the PHE flooded evaporator, it is possible that most heat transfer occurs through convective boiling rather than localized nucleate boiling, which probably affects mainly the lower section of a plate in a flooded system. This aspect could be enhanced by modifying the surface structure of the lower third of the plates in contact with the refrigerant. It is also possible that the contact points (nodes) between two adjacent plates of opposite chevron enhance nucleate boiling. Each nodal contact point could create a favorable site for a reentrant cavity.

The same applies to thermosiphon and direct-expansion evaporators. The simplest approach would be to formulate a correlation of the type proposed by Pierre (1964) for varying quality, as suggested by Baskin (1991). A positive feature about a PHE evaporator is that flow is vertical, against gravity, as opposed to horizontal flow in a shell-and-tube evaporator. Therefore, the flow regime does not get too complicated and phase separation is not a severe issue, even at low mass fluxes along the flow path, which has always been a problem in ammonia shell-and-tube DX evaporators. Generally, the profile is flat, except at the end plates. For more complete analysis, correlations could be developed that involve the local bubble point temperature concept for evaluation of wall superheat and local Froude number and boiling number Bo.

Yan and Lin's (1999) experimental study of a compact brazed exchanger (CBE) with R-134a as a refrigerant reveals some interesting features about flow evaporation in plate exchangers. Heat transfer coefficients were higher compared to circular tubes, especially at high-vapor-quality convective regimes. Mass flux played a

Licensed for single user. © 2021 ASHRAE, Inc.

significant role, whereas heat flux had very little effect on overall performance.

Ayub (2003) presents simple correlations based on design and field data collected over a decade on ammonia and R-22 direct-expansion and flooded evaporators in North America. The goal was to formulate equations that could be readily used by a design and field engineer without referral to complicated two-phase models. The correlations take into account the effect of chevron angle of the mating plates, making it a universal correlation applied to any chevron angle plate. The correlation has a statistical error of ±8%. The expression for heat transfer coefficient is

$$h = C(k_l/d_e)(\mathrm{Re}_l{}^2 h_{fg}/L_p)^{0.4124}(p_r)^{0.12}(65/\beta)^{0.35} \quad (17)$$

where $C = 0.1121$ for flooded and thermosiphons and $C = 0.0675$ for DX. This is a dimensional correlation where the values of k_l, d_e, h_{fg}, and L_p are in I-P units of Btu/h·ft·°F, ft, Btu/lb, and ft, respectively. Chevron angle β is in degrees.

Khan et al. (2010) conducted a study to investigate the boiling of NH_3(ammonia) in brazed-plate heat exchangers. Single-phase results are presented in Table 11 of Chapter 4. Two-phase evaporation experiments were aimed to investigate the effects of heat flux, mass flux, and exit vapor quality on evaporation of ammonia in a vertical plate heat exchanger at various saturation pressures.

$$\mathrm{Nu}_{tp} = C(\beta^*)\{\mathrm{Re}_{eq}\mathrm{Bo}_{eq}\}^{m(\beta^*)}\{P^*\}^{j(\beta^*)} \quad (18)$$

$$C(\beta^*) = -173.52\beta^* + 257.12$$

$$m(\beta^*) = -0.09\beta^* + 0.0005$$

$$j(\beta^*) = 0.624\beta^* - 0.822$$

2. CONDENSING

In most applications, condensation is initiated by removing heat at a solid/vapor interface, either through the walls of the vessel containing the saturated vapor or through the solid surface of a cooling mechanism placed in the saturated vapor. If sufficient energy is removed, the local temperature of vapor near the interface drops below its equilibrium saturation temperature. Because heat removal creates a temperature gradient, with the lowest temperature near the interface, droplets most likely form at this location. This defines one type of heterogeneous nucleation that can result in either dropwise or film condensation, depending on the physical characteristics of the solid surface and the working fluid.

Dropwise condensation occurs on the cooling solid surface when its surface free energy is relatively low compared to that of the liquid. Examples include highly polished or fatty-acid-impregnated surfaces in contact with steam. **Film condensation** occurs when a cooling surface with relatively high surface free energy contacts a fluid with lower surface free energy [see Chen (2003) and Isrealachvili (1991)]; this type of condensation occurs in most systems.

For smooth film flow, the rate of heat transport depends on the condensate film thickness, which depends on the rates of vapor condensation and condensate removal. At high reduced pressures (p_r), heat transfer coefficients for dropwise condensation are higher than those for film condensation at the same surface loading. At low reduced pressures, the reverse is true. For example, there is a reduction of 6 to 1 in the dropwise condensation coefficient of steam when saturation pressure decreases from 91 to 16 kPa. One method for correlating the dropwise condensation heat transfer coefficient uses nondimensional parameters, including the effect of surface tension gradient, temperature difference, and fluid properties [see, e.g., Rose (1998)].

When condensation occurs on horizontal tubes and short vertical plates, condensate film motion is laminar. On vertical tubes and long vertical plates, film motion can become turbulent. Grober et al. (1961) suggest using a Reynolds number (Re) of 1600 as the critical point at which the flow pattern changes from laminar to turbulent. This Reynolds number is based on condensate flow rate divided by the breadth of the condensing surface. For the outside of a vertical tube, the breadth is the circumference of the tube; for the outside of a horizontal tube, the breadth is twice the length of the tube. $\mathrm{Re} = 4\Gamma/\mu_l$, where Γ is the mass flow of condensate per unit of breadth, and μ_l is the absolute (dynamic) viscosity of the condensate at film temperature t_f. In practice, condensation is usually laminar in shell-and-tube condensers with the vapor outside horizontal tubes.

Vapor velocity also affects the condensing coefficient. When this is small, condensate flows primarily by gravity and is resisted by the liquid's viscosity. When vapor velocity is high relative to the condensate film, there is appreciable drag at the vapor/liquid interface. The thickness of the condensate film, and hence the heat transfer coefficient, is affected. When vapor flow is upward, a retarding force is added to the viscous shear, increasing the film thickness. When vapor flow is downward, the film thickness decreases and the heat transfer coefficient increases. For condensation inside horizontal tubes, the force of the vapor velocity causes condensate flow. When vapor velocity is high, the transition from laminar to turbulent flow occurs at Reynolds numbers lower than 1600 (Grober et al. 1961).

When **superheated** vapor is condensed, the heat transfer coefficient depends on the surface temperature. When surface temperature is below saturation temperature, using the value of h for condensation of saturated vapor that incorporates the difference between the saturation and surface temperatures leads to insignificant error (McAdams 1954). If the surface temperature is above the saturation temperature, there is no condensation and the equations for gas convection apply.

Correlation equations for condensing heat transfer, along with their applicable geometries, fluid properties, and flow rates, are given in Table 4. The basic prediction method for laminar condensation on vertical surfaces is relatively unchanged from Nusselt's (1916). Empirical relations must be used for higher condensate flow rates, however.

For condensation on the outside surface of horizontal finned tubes, use Equation (T4.5) for liquids that drain readily from the surface (Beatty and Katz 1948). For condensing steam outside finned tubes, where liquid is retained in spaces between tubes, coefficients substantially lower than those given by this equation were reported, because of the high surface tension of water relative to other liquids. For additional data on condensation on the outside of finned tubes, please refer to Webb (1994).

Condensation on Inner Surface of Tubes

Many correlations have been proposed for heat transfer during condensation in tubes. The ones validated over the widest range of data are by Cavallini et al. (2006) and Shah (2009, 2013), the latter being an extended version of the Shah (1979b) correlation. Both these correlations note that heat transfer at high flow rate is independent of heat flux, whereas at low flow rates it is affected by heat flux. These correlations apply to all flow patterns; the Shah correlation is applicable to horizontal as well as vertical tubes (with downflow), although the Cavallini et al. correlation applies only to horizontal tubes. Other well-verified correlations for horizontal tubes are those of Dobson and Chato (1998) and Thome et al. (2003). Shah (2014b) presents a flow-pattern-based version of the Shah (2013) correlation for horizontal tubes. In this version, Regime I corresponds to stratified flow, Regime II to wavy flow, and Regime III to intermittent, annular, and mist flow. Flow patterns were determined by the El Hajal et al. (2003) map. The mean deviation of the database was comparable to that of the Shah (2013) correlation.

Table 4 Heat Transfer Coefficient/Nusselt Number Correlations for Film-Type Condensation

Description	References	Equations
Vertical surfaces, height L		
Laminar, non-wavy liquid film*	Based on Nusselt (1916)	$h = 0.943\left[\frac{\rho_l g(\rho_l - \rho_v) h_{fg} k_l^3}{\mu_l L(t_{sat} - t_s)}\right]^{1/4}$ (T4.1)
$\mathrm{Re} = 4\Gamma/\mu_l < 1800$		
$\Gamma = m_l / b$ = mass flow rate of liquid condensate per unit breadth of surface		
Turbulent flow	McAdams (1954)	$h = 0.0077\left[\frac{k_l^3 \rho_l (\rho_l - \rho_v) g}{\mu_l^2}\right]^{1/3} \mathrm{Re}^{0.4}$ (T4.2)
$\mathrm{Re} = 4\Gamma/\mu_f > 1800$		
Outside horizontal tubes		
Single tube*	Dhir and Lienhard (1971)	$h = 0.729\left[\frac{\rho_l g(\rho_l - \rho_v) h_{fg} k_l^3}{\mu_l D(t_{sat} - t_s)}\right]^{1/4}$ (T4.3)
$\mathrm{Re} = 4\Gamma/\mu_l < 3600$		
N tubes, vertically aligned	Murase et al. (206)	$h = h_D N^{-1/n}$ (T4.4)
		h_D is the heat transfer coefficient for one tube calculated from Dhir and Lienhard (1971) and the value of n can vary between 4 and 6.
Finned tubes	Beatty and Katz (1948)	$h = 0.689\left[\frac{\rho_l^2 k_l^3 g h_{fg}}{\mu_l (t_{sat} - t_s) D_e}\right]^{1/4}$ (T4.5)
This correlation is acceptable for low-surface-tension fluids and low-fin-density tubes. It overpredicts in cases where space between tubes floods with liquid (as when either surface tension becomes relatively large or fin spacing relatively small).		$\frac{1}{D_e^{1/4}} = 1.30\frac{A_s \phi}{A_{eff} L_{mf}^{1/4}} + \frac{A_p}{A_{eff} D^{1/4}}$
		$A_{eff} = A_s\phi + A_p$, $L_{mf} = \pi(D_o^2 - D_r^2)/D_o$
		ϕ = fin efficiency
		D_o = outside tube diameter (including fins)
		D_r = diameter at fin root (i.e., smooth tube outer diameter)
		A_s = fin surface area
		A_p = surface area of tube between fins
Internal flow in plain channels		
Horizontal, vertical downflow in round, rectangular, triangular, semicircular, single, and multiport channels	Shah (2009, 2013, 2016c)	Condensing heat transfer coefficient h_{TP} is given by the following equations: (T4.6)
D_h = 0.10 to 49 mm		In Regime I, $h_{TP} = h_I$
p_r = 0.0008 to 0.946		In Regime II, $h_{TP} = h_I + h_{Nu}$
G = 4 to 1400 kg/(m²·s)		In Regime III, $h_{TP} = h_{Nu}$
x = 0.01 to 0.99		$h_I = h_{LS}\left(1 + \frac{3.8}{Z^{0.95}}\right)\left(\frac{\mu_l}{14\mu_v}\right)^{0.0058 + 0.557 p_r}$
30 fluids, including water, hydrocarbons, new and old halocarbon refrigerants, CO_2		$h_{\mathrm{Nu}} = 1.32\mathrm{Re}_{LS}^{-1/3}\left[\frac{\rho_l(\rho_l - \rho_v) g k_l^3}{\mu_l^2}\right]^{1/3}$
		$h_{LT} = 0.023\ \mathrm{Re}_{LS}^{0.8}\ \mathrm{Pr}_f^{0.4}\frac{k_f}{D}$
		$\mathrm{Re}_{LT} = GD/\mu_l$ $\mathrm{Re}_{LS} = GD(1-x)/\mu_l$
		$\mathrm{Re}_{\mathrm{GS}} = GDx/\mu_v$ $\mathrm{We}_g = G^2 D_h/(\rho_g \sigma)$
		For horizontal tubes,
		Regime III if
		$J_g \le 0.95(1.254 + 2.27Z^{1.249})^{-1}$
		$J_g = \frac{xG}{[gD\rho_v(\rho_l - \rho_v)]^{0.5}}$
		Regime I if $\mathrm{We}_g > 100$ and
		$J_g \ge 0.98(Z + 0.263)^{-0.62}$
		Else Regime II
		For vertical downflow,
		Regime I if
		$J_g \ge (2.4Z + 0.73)^{-1}$
		Regime III if
		$J_g \le 0.89 - 0.93\exp(-0.087Z^{-1.17})$
		Else Regime II
		$Z = (1/x - 1)^{0.8}\ p_r^{0.4}$

Table 4 Heat Transfer Coefficient/Nusselt Number Correlations for Film-Type Condensation (*Continued*)

Description	References	Equations
		All properties at saturation temperature. For noncircular channels, equivalent diameter is based on cooled perimeter in all equations except We_g, which uses hydraulic diameter D_h.
Horizontal tubes D = 3.1 to 17.0 mm G = 40 to 2240 kg/(m^2·s) t_s = 24 to 302°C Fluids: water, halocarbons, hydrocarbons, CO_2	Cavallini et al. (2006)	$J_{g,t} = \left\{ \left[7.5 / \left(4.3 X_{tt}^{1.111} + 1 \right) \right]^{-3} + C_T^{-3} \right\}^{-1/3}$ (T4.7) C_T = 1.6 for hydrocarbons, 2.6 for all other fluids If $J_g > J_{g,t}$ $h_{TP} = h_A$ $h_A = h_{LT}[1 + 1.128x^{0.8170}(\rho_f/\rho_g)^{0.3685}B]$ $B = (\mu_f/\mu_g)^{0.2363}(1 - \mu_g/\mu_f)^{2.144}\,\mathrm{Pr}_f^{-0.1}$ If $J_g < J_{g,t}$, $h_{TP} = [h_A(J_{g,t}/J_g)^{0.8} - h_{st}](J_g/J_{g,t}) + h_{st}$ $h_{st} = 0.725\{1 + 0.741[(1-x)/x]^{0.3321}\}^{-1}$ $\times \{k_f^3 \rho_f(\rho_f - \rho_g) g h_{fg}/[\mu_f D(t_w - t_s)]\}^{0.25}$ $+ (1 - x^{0.087}) h_{LT}$
Horizontal mini/micro (D < 3 mm) round, rectangular, triangular, semicircular, single, and multiport channels D_h = 0.1 to 2.8 mm, p_r = 0.0055 to 0.942, G = 20 to 1400 kg/(m^2·s)	Shah (2016c)	Same as preceding Shah correlation except replace h_l with h_A from the Cavallini et al. correlation [Equation (T4.7)].
Inclined tubes Inclination θ = –90 to +90 degree (–90 vertical down, 0 horizontal), D = 1.2 to 14.8 mm, p_r = 0.006 to 0.43.	Shah (2015d)	For θ = –30 to +90, $h_{TP,\theta} = h_{TP,0}$ For θ = –90 to –30, $h_{TP,\theta} = h_{TP,0} + (h_{TP,0} - h_{TP,-90})(\theta + 30)/60$

Note: Properties in Equation (T4.1) evaluated at $t_f = (t_{sat} + t_s)/2$; h_{fg} evaluated at t_{sat}. *For increased accuracy, use $h'_{fg} = h_{fg} + 0.68 c_{p,l}(t_{sat} - t_s)$ in place of h_{fg}.

Use caution in applying any of these correlations to carbon dioxide. Shah (2015c) compared a wide range of data for condensation of CO_2 with several well-verified general correlations. The Shah (2009, 2013) correlation gave good agreement with data for mass flux up to 300 kg/(m^2·s); its agreement with data at higher flow rates was inconsistent. None of the other correlations gave good agreement at any flow rate. Researchers have generally indicated high uncertainties in their measurements, so it is unclear which are inaccurate: data or correlations.

Some condensers have **inclined tubes** (i.e., flow direction is not horizontal or vertically down). Literature on condensation in inclined tubes was reviewed in detail by Lips and Meyer (2011) and briefly by Meyer et al. (2014). They reported that data from different sources showed different effects of inclination on heat transfer, and that no general method of prediction was available. Shah (2015d) gave a model for variation of heat transfer with inclination (Table 4). Together with the Shah correlation (2009, 2013), it gave good agreement with data from six sources (all that could be found), with mean absolute deviation of 15.7%. Note that, for upward flow, only data for cocurrent flow of condensate and vapor (i.e., flows above flooding limit) were considered.

During upward flow of vapor at low velocities (below flooding velocity), condensate flows downwards while the vapor is flowing upwards. Reflux condensers are examples. Lips and Meyer (2011) reviewed the literature on this subject; of the many experimental studies and various predictive techniques examined, none was sufficiently verified to be considered generally applicable. Palen and Yang (2001) reviewed the literature on predicting flooding velocity in reflux condensers.

Mini- and Microchannels. (See the section on Mini- and Microchannels, under Forced-Convection Evaporation in Tubes, for definitions of these channels.) Much research has been done on condensation in small channels [e.g., Awad et al. (2014)]. Many theoretical and empirical formulas have been proposed, but the only ones that have been verified with a wide range of data from many sources are by Kim and Mudawar (2013) and Shah (2016c). Kim and Mudawar (2013) presented a flow pattern based model that showed good agreement with a wide-ranging database including many fluids, horizontal and vertical channels, and hydraulic diameters from 0.424 to 6.22 mm. Shah (2016c) compared a wide range of data for horizontal channels of diameter less than 3 mm with the Shah (2013) general correlation, and found good agreement with all data except for We_g < 100, which were underpredicted. Satisfactory agreement was achieved by using Regime II instead of Regime I for such data. Thus, this modified correlation is applicable to both mini and conventional channels. Shah (2016c) also gave a new correlation in which Cavallini et al.'s (2006) heat-flux-independent regime replaced the corresponding formula in the Shah correlation. The mean absolute deviations of the Kim and Mudawar, modified Shah, and the new Shah correlations were 18.6, 17.8, and 14.6%, respectively, compared to data for single channels. Thus, the new Shah correlation is significantly more accurate than the other two and is therefore preferable.

Multicomponent Mixtures. Many refrigerants in use or in development are mixtures of pure fluids. Heat transfer in condensation of mixtures is reduced by resistance caused by mass transfer effects. The phenomena involved are complex, but Bell and Ghaly (1973) presented a simple method to estimate this resistance. It is given by the following equation:

$$\frac{1}{h_{mix}} = \frac{1}{h_c} + \frac{Y}{h_{GS}} \tag{19}$$

$$Y = xC_{pg}\frac{dt_{dew}}{dH} \tag{20}$$

where h_{mix} is the heat transfer coefficient of the mixture, h_c is the heat transfer coefficient for condensation of an equivalent pure fluid

Licensed for single user. © 2021 ASHRAE, Inc.

with the properties of the mixture, and H is enthalpy. The single-phase heat transfer coefficient h_{GS} is to be calculated conservatively. Shah et al. (2013) used this method together with the Shah correlation (2009), the single-phase heat transfer coefficient h_{GS} being calculated by the following equation:

$$h_{GS} = 0.023\left(\frac{GxD}{\mu_g}\right)^{0.8}\frac{\mathrm{Pr}_g^{0.4}k_g}{D} \tag{21}$$

It was compared to 529 test points for 36 refrigerant mixtures from 22 studies in horizontal and vertical tubes that included temperature glides up to 35.5 K. The mean absolute deviation was 18%. This method is recommended.

Plate-Type Condensers. ASHRAE-sponsored research project RP-1394 examined carbon dioxide condensation in brazed-plate heat exchangers (BPHEs) (Jokar and Hayes 2009). Three BPHEs with different interior configurations, each consisting of three channels, were tested (see Figure 25 in Chapter 4). The single-phase results of this study are presented in Table 11 of Chapter 4 and in Hayes and Jokar (2009). For the two-phase analysis, carbon dioxide was the working fluid, flowing through the middle channel, while the cooling fluid flowed through the side channels of the three different exchangers. Condensation of carbon dioxide occurred at saturation temperatures ranging from –17.8°C to –34.4°C at heat fluxes spanning 2.5 to 15.7 kW/m^2 (Hayes et al. 2011, 2012). The proposed correlations are summarized as follows, where the uncertainty of the two-phase correlations was less than 8%:

$$\mathrm{Nu}_{tp} = C_1\,\mathrm{Re}_l^{C_2}\mathrm{Pr}_l^{C_3}\left(\frac{G^2}{\rho_l^2 c_{p,l}\Delta T}\right)^{C_4}\left(\frac{\rho_l^2 i'_{fg}}{G^2}\right)^{C_5}\left(\frac{\rho_l\sigma_l}{\mu_l G}\right)^{C_6}\left(\frac{\rho_l}{\rho_l-\rho_v}\right)^{C_7}$$

Plate	C_1	C_2	C_3	C_4	C_5	C_6	C_7
60/60	0.37	0.706	0.35	1.07	0.91	0.032	1.18
27/60	0.16	0.727	0.35	1.07	0.90	0.147	1.00
27/27	0.11	0.771	0.35	1.04	0.92	0.0105	2.00

Longo et al.'s (2014) correlation for condensation inside corrugated plate type heat exchangers was shown to agree with data from several sources for several halocarbon and hydrocarbon refrigerants, as well as CO_2.

Noncondensable Gases. Condensation heat transfer rates reduce drastically if one or more noncondensable gases are present in the condensing vapor/gas mixture. In mixtures, the condensable component is called *vapor* and the noncondensable component is called *gas*. As the mass fraction of gas increases, the heat transfer coefficient decreases in an approximately linear manner. Othmer (1929) found that the heat transfer coefficient in a steam chest with 2.89% air by volume dropped from about 11.4 to about 3.4 kW/(m^2·K).

Consider a surface cooled to temperature t_s below the saturation temperature of the vapor (Figure 8). In this system, accumulated condensate falls or is driven across the condenser surface. At a finite heat transfer rate, the temperature profile across the condensate can be estimated from Table 4; the interface of the condensate is at a temperature $t_{if} > t_s$. In the absence of gas, the interface temperature is the vapor saturation temperature at the pressure of the condenser.

The presence of noncondensable gas lowers the vapor partial pressure and hence the saturation temperature of the vapor in equilibrium with the condensate. Further, vapor movement toward the cooled surface implies similar bulk motion of the gas. At the condensing interface, vapor condenses at temperature t_{if} and is then swept out of the system as a liquid. The gas concentration rises to ultimately diffuse away from the cooled surface at the same rate as

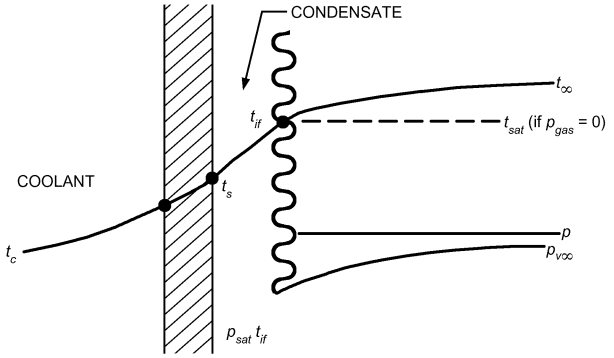

Fig. 8 Origin of Noncondensable Resistance

it is convected toward the surface (Figure 8). If the gas (mole fraction) concentration is Y_g and total pressure of the system is p, the partial pressure of the bulk gas is

$$p_{g\infty} = Y_{g\infty}p \tag{22}$$

The partial pressure of the bulk vapor is

$$p_{v\infty} = (1 - Y_{g\infty})p = Y_v p \tag{23}$$

As opposing fluxes of convection and diffusion of the gas increase, the partial pressure of gas at the condensing interface is $p_{gif} > p_{g\infty}$. By Dalton's law, assuming isobaric conditions,

$$p_{gif} + p_{vif} = p \tag{24}$$

Hence, $p_{vif} < p_{v\infty}$.

Sparrow et al. (1967) noted that thermodynamic equilibrium exists at the interface, except in the case of very low pressures or liquid metal condensation, so that

$$p_{vif} = p_{sat}(t_{if}) \tag{25}$$

where $p_{sat}(t)$ is the saturation pressure of vapor at temperature t. The available Δt for condensation across the condensate film is reduced from $(t_\infty - t_s)$ to $(t_{if} - t_s)$, where t_∞ is the bulk temperature of the condensing vapor/gas mixture, caused by the additional noncondensable resistance.

Equations in Table 4 are still valid for condensate resistance, but interface temperature t_{if} must be found. The noncondensable resistance, which accounts for the temperature difference $(t_\infty - t_{if})$, depends on heat flux (through the convecting flow to the interface) and diffusion of gas away from the interface.

For simple cases, Rose (1969), Sparrow and Lin (1964), and Sparrow et al. (1967) found solutions to the combined energy, diffusion, and momentum problem of noncondensables, but they are cumbersome.

A general method given by Colburn and Hougen (1934) can be used over a wide range if correct expressions are provided for the rate equations; add the contributions of sensible heat transport through the noncondensable gas film and latent heat transport via condensation:

$$\begin{aligned} h_g(t_\infty - t_{if}) + K_D M_v h_{fg}(p_{v\infty} - p_{vif}) &= h(t_{if} - t_s) \\ &= U(t_{if} - t_c) \end{aligned} \tag{26}$$

where h is from the appropriate equation in Table 4.

Licensed for single user. © 2021 ASHRAE, Inc.

The value of the heat transfer coefficient for stagnant gas depends on the geometry and flow conditions. For flow parallel to a condenser tube, for example,

$$j = \left[\frac{h_g}{(c_p)_g G}\right]\left[\frac{(c_p)_g \mu_{gv}}{K_{Dg}}\right]^{2/3} \tag{27}$$

where j is a known function of Re = GD/μ_{gv}. The mass transfer coefficient K_D is

$$\frac{K_D}{M_m}\left[\frac{p_{g\infty} - p_{gif}}{\ln(p_{g\infty}/p_{gif})}\right]\left(\frac{\mu_{gv}}{\rho_g D}\right)^{2/3} = j \tag{28}$$

The calculation method requires substitution of Equation (28) into Equation (26). For a given flow condition, G, Re, j, M_m, $\rho_{g\infty}$, h_g, and h (or U) are known. Assume values of t_{if}; calculate $p_{sat}(t_{if}) = p_{vif}$ and hence p_{gif}. If t_s is not known, use the overall coefficient U to the coolant and t_c in place of h and t_s in Equation (26). For either case, at each location in the condenser, iterate Equation (26) until it balances, giving the condensing interface temperature and, hence, the thermal load to that point (Colburn 1951; Colburn and Hougen 1934). For more detail, refer to Chapter 10 in Collier and Thome (1996).

Other Impurities

Vapor entering the condenser often contains a small percentage of impurities such as oil. Oil forms a film on the condensing surfaces, creating additional resistance to heat transfer. Some allowance should be made for this, especially in the absence of an oil separator or when the discharge line from the compressor to the condenser is short.

3. PRESSURE DROP

Total pressure drop for two-phase flow in tubes consists of friction, change in momentum, and hydrostatic components:

$$\left(\frac{dp}{dz}\right)_{total} = \pm\left(\frac{dp}{dz}\right)_{static} + \left(\frac{dp}{dz}\right)_{mom} + \left(\frac{dp}{dz}\right)_{fric} \tag{29a}$$

where

$$\left(\frac{dp}{dz}\right)_{static} = [\varepsilon_v \rho_v + (1-\varepsilon_v)\rho_l] g \sin\theta$$

The momentum pressure drop accounts for the acceleration of the flow, usually caused by evaporation of liquid or condensation of vapor. In this case,

$$\left(\frac{dp}{dz}\right)_{mom} = G^2\left(\frac{x^2}{\varepsilon_v \rho_v} + \frac{(1-x)^2}{(1-\varepsilon_v)\rho_l}\right) \tag{29b}$$

where G is total mass velocity. An empirical model for the void fraction with good accuracy is presented by Steiner (1993), based on the (dimensional) correlation of Rouhani and Axelsson (1970).

$$\varepsilon_v = \frac{x}{\rho_v}\left\{[1 + 0.12(1-x)]\left(\frac{x}{\rho_v} + \frac{1-x}{\rho_l}\right) + \left[\frac{1.18(1-x)[g\sigma(\rho_l - \rho_v)]^{0.25}}{G^1 \rho_l^{0.5}}\right]\right\}^{-1} \tag{29c}$$

Table 5 Constants in Equation (29d) for Different Void Fraction Correlations

Model	A_l	q_l	r_l	S_l
Homogeneous (Collier 1972)	1.0	1.0	1.0	0
Lockhart and Martinelli (1949)	0.28	0.64	0.36	0.07
Baroczy (1963)	1.0	0.74	0.65	0.13
Thome (1964)	1.0	1.0	0.89	0.18
Zivi (1964)	1.0	1.0	0.67	0
Turner and Wallis (1965)	1.0	0.72	0.40	0.08

A generalized expression for ε_v was suggested by Butterworth (1975):

$$\varepsilon_v = \left[1 + A_l\left(\frac{1-x}{x}\right)^{q_l}\left(\frac{\rho_v}{\rho_l}\right)^{r_l}\left(\frac{\mu_l}{\mu_v}\right)^{S_l}\right]^{-1} \tag{29d}$$

This generalized form represents the models of several researchers; constants and exponents needed for each model are given in Table 5. Consult Woldesemayat and Ghajar (2007) for a summary of 68 void fraction correlations for different flow patterns in horizontal and upward-inclined pipes.

The homogeneous model provides a simple method for computing the acceleration and gravitational components of pressure drop. It assumes that flow can be characterized by average fluid properties and that the velocities of liquid and vapor phases are equal (Collier and Thome 1996; Wallis 1969). The following discussion of several empirical correlations for computing frictional pressure drop in two-phase internal flow is based on Ould Didi et al. (2002).

Friedel Correlation

A common strategy in both two-phase heat transfer and pressure drop modeling is to begin with a single-phase model and determine an appropriate **two-phase multiplier** to correct for the enhanced energy and momentum transfer in two-phase flow. The Friedel (1979) correlation follows this strategy:

$$\frac{dp}{dz_{fric}} = \left(\frac{dp}{dz}\right)_{lo} \Phi_{lo}^2 \tag{30a}$$

In this case,

$$\left(\frac{dp}{dz}\right)_{lo} = 4 f_l \frac{G_{tot}^2}{2\rho_l D} \tag{30b}$$

with

$$f = \frac{0.079}{\mathrm{Re}^{0.25}} \tag{30c}$$

and

$$\mathrm{Re} = \frac{G_{tot} D}{\mu} \tag{30d}$$

with $\mu = \mu_l$ used to calculate f_l for use in Equation (30b). The two-phase multiplier Φ_{lo}^2 is determined by

$$\Phi_{lo}^2 = E + \frac{3.24FH}{\mathrm{Fr}_h^{0.045}\mathrm{We}_l^{0.035}} \tag{30e}$$

where

$$\mathrm{Fr}_h = \frac{G_{tot}^2}{gD\rho_h^2} \tag{30f}$$

Licensed for single user. © 2021 ASHRAE, Inc.

$$E = (1-x)^2 + x^2\left(\frac{\rho_l}{\rho_v}\right)\left(\frac{f_v}{f_l}\right) \tag{30g}$$

$$F = x^{0.78}(1-x)^{0.224} \tag{30h}$$

$$H = \left(\frac{\rho_l}{\rho_v}\right)^{0.91}\left(\frac{\mu_v}{\mu_l}\right)^{0.19}\left(1-\frac{\mu_v}{\mu_l}\right)^{0.7} \tag{30i}$$

$$\mathrm{We}_l = \frac{G_{tot}^2 D}{\sigma_t \rho_h} \tag{30j}$$

Note that friction factors in Equation (30g) are calculated from Equations (30c) and (30d) using the vapor and liquid fluid properties, respectively. The homogeneous density ρ_h is given by

$$\rho_h = \left(\frac{x}{\rho_v} + \frac{1-x}{\rho_l}\right)^{-1} \tag{30k}$$

This method is generally recommended when the viscosity ratio μ_l/μ_v is less than 1000.

Lockhart and Martinelli Correlation

One of the earliest two-phase pressure drop correlations was proposed by Martinelli and Nelson (1948) and rendered more useful by Lockhart and Martinelli (1949). A relatively straightforward implementation of this model requires that Re_l be calculated first, based on Equation (23d) and liquid properties. If $\mathrm{Re}_l > 4000$,

$$\left(\frac{dp}{dz}\right)_{fric} = \Phi_{ltt}^2\left(\frac{dp}{dz}\right)_l \tag{31a}$$

where

$$\Phi_{ltt}^2 = 1 + \frac{C}{X_{tt}} + \frac{1}{X_{tt}^2} \tag{31b}$$

and $(dp/dz)_l$ is calculated using Equation (30b).

If $\mathrm{Re}_l < 4000$,

$$\frac{dp}{dz} = \Phi_{Vtt}^2\left(\frac{dp}{dz}\right)_v \tag{31c}$$

where

$$\Phi_{Vtt}^2 = 1 + CX_{tt} + X_{tt}^2 \tag{31d}$$

In both cases,

$$X_{tt} = \left(\frac{1-x}{x}\right)^{0.9}\left(\frac{\rho_v}{\rho_l}\right)^{0.5}\left(\frac{\mu_l}{\mu_v}\right)^{0.1} \tag{31e}$$

and the subscript *tt* means turbulence in both liquid and vapor phases and $C = 20$ for most cases of interest in internal flow in HVAC&R systems.

Grönnerud Correlation

Much of the two-phase pressure drop modeling has been based on adiabatic air/water data. To address this, Grönnerud (1979) developed a correlation based on refrigerant flow data, also using a two-phase multiplier:

$$\left(\frac{dp}{dz}\right)_{fric} = \Phi_{lo}\left(\frac{dp}{dz}\right)_{lo} \tag{32a}$$

with

$$\Phi_{lo} = 1 + \left(\frac{dp}{dz}\right)_{\mathrm{Fr}}\left[\frac{(\rho_l/\rho_v)}{(\mu_l/\mu_v)^{0.25}} - 1\right] \tag{32b}$$

The liquid-only pressure gradient in Equation (32a) is calculated as before, using Equation (30b) with $x = 0$ and

$$\left(\frac{dp}{dz}\right)_{\mathrm{Fr}} = f_{\mathrm{Fr}}\left[x + 4\left(x^{1.8} - x^{10} f_{\mathrm{Fr}}^{0.5}\right)\right] \tag{32c}$$

The friction factor f_{Fr} in this method depends on the liquid Froude number, defined by

$$\mathrm{Fr}_l = \frac{G_{tot}^2}{gD\rho_l^2} \tag{32d}$$

If Fr_l is greater than or equal to 1, $f_{\mathrm{Fr}} = 1.0$. If $\mathrm{Fr}_l < 1$,

$$f_{\mathrm{Fr}} = \mathrm{Fr}_l^{0.3} + 0.0055\left[\ln\left(\frac{1}{\mathrm{Fr}_l}\right)\right]^2 \tag{32e}$$

Müller-Steinhagen and Heck Correlation

A simple, purely empirical correlation was proposed by Müller-Steinhagen and Heck (1986):

$$\left(\frac{dp}{dz}\right)_{fric} = \Lambda(1-x)^{1/3} + \left(\frac{dp}{dz}\right)_{vo} x^3 \tag{33a}$$

where

$$\Lambda = \left(\frac{dp}{dz}\right)_{lo} + 2\left[\left(\frac{dp}{dz}\right)_{vo} - \left(\frac{dp}{dz}\right)_{lo}\right]x \tag{33b}$$

and

$$\left(\frac{dp}{dz}\right)_{lo} = f_l\frac{2G_{tot}^2}{D\rho_l} \tag{33c}$$

$$\left(\frac{dp}{dz}\right)_{vo} = f_v\frac{2G_{tot}^2}{D\rho_v} \tag{33d}$$

where the subscript *vo* means vapor flow only and friction factors in Equations (33c) and (33d) are again calculated from Equations (30c) and (30d) using the liquid and vapor properties, respectively.

Wallis Correlation

The general nature of annular vapor/liquid flow in vertical pipes is indicated in Figure 9 (Wallis 1970), which plots the effective vapor friction factor versus the liquid fraction $(1 - \varepsilon_v)$, where ε_v is the vapor void fraction as defined by Equations (29c) or (29d).

The effective vapor friction factor in Figure 9 is defined as

$$f_{eff} = \left[\frac{\varepsilon_v^{2.5} D}{2\rho_v\left(\frac{4Q_v}{\pi D^2}\right)^2}\right]\left(\frac{dp}{dz}\right) \tag{34a}$$

where D is pipe diameter, ρ_v is vapor density, and Q_v is vapor volumetric flow rate. The friction factor of vapor flowing by itself in the pipe (presumed smooth) is denoted by f_v. Wallis' analysis of the flow occurrences is based on interfacial friction between the gas and liquid. The wavy film corresponds to a conduit with roughness height of about four times the liquid film thickness. Thus, the pressure drop relation for vertical flow is

Licensed for single user. © 2021 ASHRAE, Inc.

$$\left(\frac{dp}{dz}\right)_{fric} = 0.01\left(\frac{\rho_v}{D^5}\right)\left(\frac{4Q_v}{\pi}\right)^2\left[\frac{1+75(1-\varepsilon_v)}{\varepsilon_v^{2.5}}\right] \quad (34b)$$

This corresponds to the Martinelli-type analysis with

$$f_{TP} = \Phi_v^2 f_v \quad (34c)$$

when

$$\Phi_v^2 = \frac{1+75(1-\varepsilon_v)}{\varepsilon_v} \quad (34d)$$

The friction factor f_v (of vapor alone) is taken as 0.02, an appropriate turbulent flow value. This calculation can be modified for more detailed consideration of factors such as Reynolds number variation in friction, gas compressibility, and entrainment (Wallis 1970).

Recommendations

Although many references recommend the Lockhart and Martinelli (1949) correlation, recent reviews of pressure drop correlations found other methods to be more accurate. Tribbe and Müller-Steinhagen (2000) found that the Müller-Steinhagen and Heck (1986) correlation worked quite well for a database of horizontal flows that included air/water, air/oil, steam, and several refrigerants. Ould Didi et al. (2002) also found that this method offered accuracies nearly as good or better than several other models; the Friedel (1979) and Grönnerud (1979) correlations also performed favorably. Note, however, that mean deviations of as much as 30% are common using these correlations; calculations for individual flow conditions can easily deviate 50% or more from measured pressure drops, so use these models as approximations only.

Evaporators and condensers often have valves, tees, bends, and other fittings that contribute to the overall pressure drop of the heat exchanger. Collier and Thome (1996) summarize methods predicting the two-phase pressure drop in these fittings.

Pressure Drop in Microchannels

Chisholm and Laird (1958) related the friction multiplier to the Lockhart-Martinelli parameter through a simple expression that depends on the coefficient C ranging from 5 to 20, depending on laminar or turbulent flow of vapor and liquid. Some researchers suggest empirical correlations for the coefficient C to determine the two-phase friction multiplier; among the most widely used are Lee and Lee's (2001) and Mishima and Hibiki's (1996). Mishima and Hibiki's correlation appears to provide a compact/simple correlation for adiabatic two-phase flow for tube diameters of 0.21 to 6.05 mm, but its applicability to microchannel flows with phase change has not yet been demonstrated. It proposes

$$C = 21\left(1 - e^{-0.319 d_h}\right) \quad (35)$$

where diameter d_h is in millimetres. Cavallini et al. (2005) showed that Mishima and Hibiki's method could predict two-phase pressure drop for flow condensation of refrigerants R-134a and R-236ea in 1.4 mm minitubes. The correlation of Mishima and Hibiki (1996) evidently assumes that C depends on channel size only. Based on the observation that C depends on phase mass fluxes as well, and using experimental data from several sources as well as their own data that covered channel gaps in the 0.4 to 4 mm range, Lee and Lee (2001) derived the following correlation for C, for adiabatic flow in horizontal thin rectangular channels:

$$C = A\left(\frac{\mu_l^2}{\rho_l \sigma d_h}\right)^q \left(\frac{\mu_l j}{\sigma}\right)^r \mathrm{Re}_{l0}^S \quad (36)$$

where $j = G[(1-x)/\rho_l + x/\rho_g)]$ and represents the total mixture volumetric flux. The constants A, r, q, and s depend on the liquid and

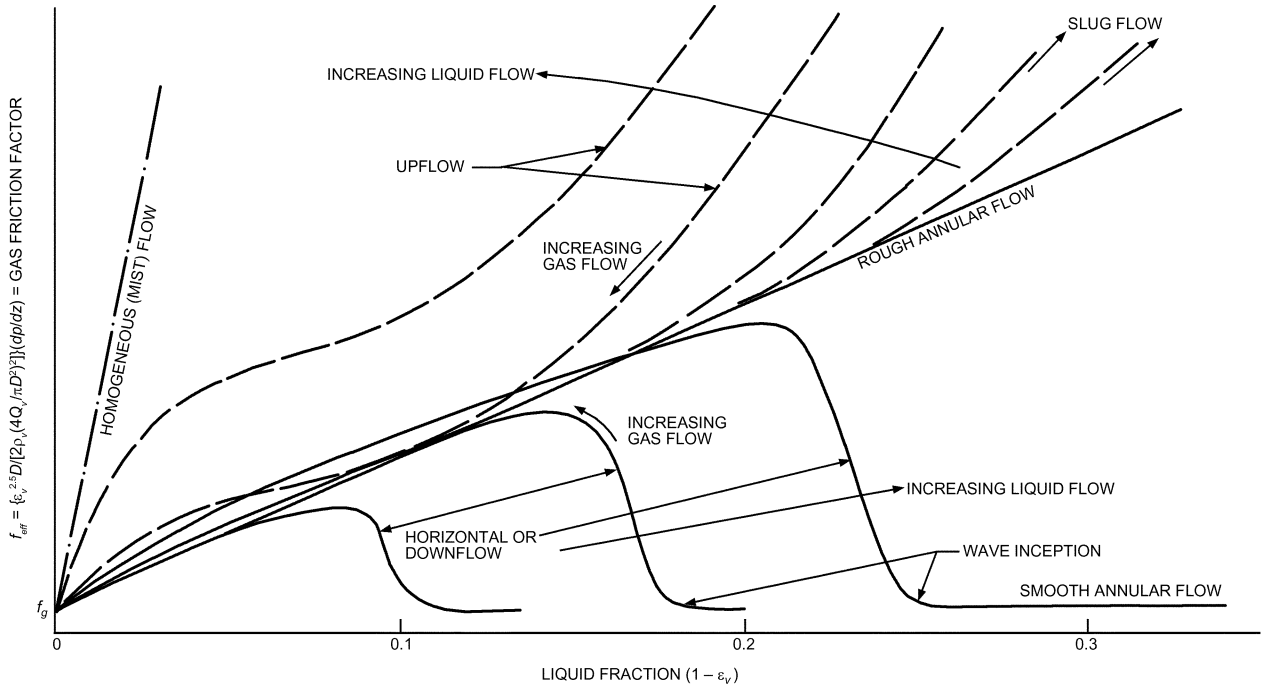

Fig. 9 Qualitative Pressure Drop Characteristics of Two-Phase Flow Regime

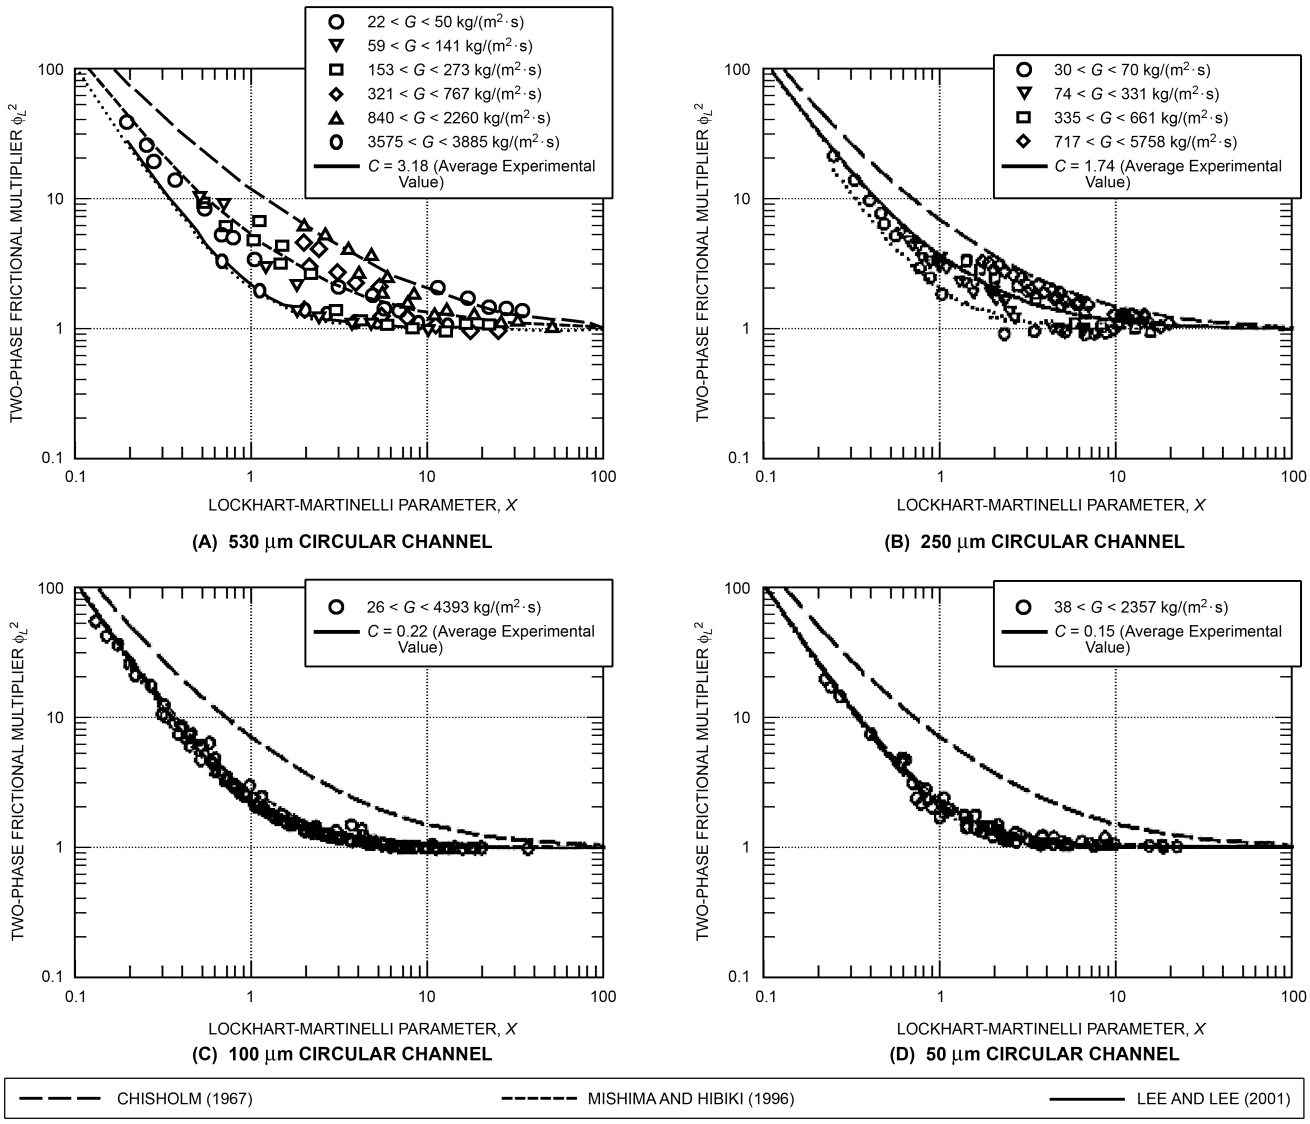

Fig. 10 Pressure Drop Characteristics of Two-Phase Flow: Variation of Two-Phase Multiplier with Lockhart-Martinelli Parameter
(Chung and Kawaji 2004)

Table 6 Constant and Exponents in Correlation of Lee and Lee (2001)

Liquid Regime	Gas Flow Regime	*A*	*q*	*r*	*s*
Laminar	Laminar	6.833×10^{-8}	–1.317	0.719	0.577
Laminar	Turbulent	6.185×10^{-2}	0	0	0.726
Turbulent	Laminar	3.627	0	0	0.174
Turbulent	Turbulent	0.408	0	0	0.451

gas flow regimes (viscous-dominated or turbulent), as listed in Table 6.

The correlations of Lee and Lee (2001) and Mishima and Hibiki (1996) [Equations (36) and (35), respectively] predicted the data of (1) Chung et al. (2004) for adiabatic flow of water and nitrogen in horizontal 96 μm square rectangular microchannels, (2) Zhao and Bi (2001) for water and airflow in a miniature triangular channel with d_h = 0.87 to 2.89 mm, and (3) Chung and Kawaji (2004) for water and nitrogen flow in a horizontal circular channel with d_h = 50 to 530 μm, within about ±10%. Figure 10 shows the two-phase friction multiplier data plotted against the Lockhart-Martinelli parameter for the data of Chung and Kawaji (2004). Further detailed information for pressure drop in microchannels can be found in Ohadi et al. (2013).

Pressure Drop in Plate Heat Exchangers

For a description of plate heat exchanger geometry, see the Plate Heat Exchangers section of Chapter 4.

Ayub (2003) presented simple correlations for Fanning friction factor based on design and field data collected over a decade on ammonia and R-22 DX and flooded evaporators in North America. The goal was to formulate equations that could be readily used by a design and field engineer without reference to complicated two-phase models. Correlations within the plates are formulated as if the entire flow were saturated vapor. The correlation is accordingly adjusted for the chevron angle, and thus generalized for application to any type of commercially available plate, with a statistical error of ±10%:

Licensed for single user. © 2021 ASHRAE, Inc.

$$f = (n/\mathrm{Re}^m)(-1.89 + 6.56R - 3.69R^2) \quad (37)$$

for $30 \le \beta \le 65$ where $R = (30/\beta)$, and β is the chevron angle in degrees. The values of m and n depend on Re.

m	n	Re
0.137	2.99	<4000
0.172	2.99	4000 < Re < 8000
0.161	3.15	8000 < Re < 16 000
0.195	2.99	>16 000

Pressure drop within the port holes is correlated as follows, treating the entire flow as saturated vapor:

$$\Delta p_{port} = 0.0076 \rho V^2/2g \quad (38)$$

This equation accounts for pressure drop in both inlet and outlet refrigerant ports and gives the pressure drop in I-P units of lb/in^2 with input for ρ in lb/ft^3, V in ft/s, and g in ft/s^2. For evaporation of NH_3 in brazed-plate heat exchangers (BPHEs), Khan et al. (2012a, 2012b, 2014) correlated the friction factor with flow conditions.

$$f_{TP} = C(\mathrm{Re}_{eq})^m (p^*)^j \quad (39)$$

	60°/60°	60°/30°	30°/30°
C	673,336	305,590	212
m	–1.29	–1.26	–0.51
j	0.9	0.9	0.53

ASHRAE research project RP-1394 also established the following correlation for the carbon dioxide condensation in BPHEs (Jokar and Hayes 2009).

$$C_{F,TP} = C\,\mathrm{Re}^{-P} \quad (40)$$

Plate	C	P
60/60	1837.4	0.817
27/60	10.65	0
27/27	1221.3	0.815

Microengineered Surfaces for Enhanced Heat Transfer. Enhanced heat transfer surfaces are used in heat exchangers to improve performance while keeping pressure drops under control, with the net result of reduced footprint and/or mass or volume reductions and savings in capital and/or life-cycle costs. Condensing heat transfer is often enhanced with circular fins attached to the external surfaces of tubes to increase the heat transfer area. The latest generations of condensing surfaces have three-dimensional features (e.g., notches, wings) designed to promote good drainage of condensed liquid while extending the available heat transfer surface area, thus giving higher condensation heat transfer coefficients and condenser capacity. Similar enhancement methods (e.g., porous coatings, integral fins, reentrant cavities, other three-dimensional surface textures) are used to augment boiling/evaporation heat transfer on external surfaces of evaporator surfaces. Webb (1981) surveyed external boiling surfaces and compared performances of several enhanced surfaces with performance of smooth tubes. For some heat exchangers, the heat transfer coefficient for the refrigerant side is often smaller than the coefficient for the water side. Thus, enhancing the refrigerant-side surface can reduce the size of the heat exchanger and improve its performance. Most recent heat exchanger designs have augmentation on both liquid and refrigerant sides so as to avoid one side limiting the other's performance.

Internal fins and heat transfer surfaces can increase the heat transfer coefficients during evaporation or condensation in tubes. However, such enhanced features may often increase refrigerant pressure drop and reduce the heat transfer rate by decreasing the available temperature difference between hot and cold fluids, thus requiring careful design and optimization studies. For a review of internal enhancements for two-phase heat transfer, including the effects of oil, see Newell and Shah (2001). For additional information on enhancement methods in two-phase flow, see Bergles (1976, 1985), Thome (1990), and Webb (1994).

Perhaps the most effective mode of boiling heat transfer is thin-film evaporation, which maintains a thin film on the heat transfer surface at all times to avoid hot spots. The heat transfer coefficient of thin-film evaporation is directly proportional to thermal conductivity of the fluid over the film thickness; thus, the thinner the film, the higher the resulting heat transfer coefficients. Heat transfer coefficients can be several orders of magnitude larger, compared to conventional pool and convective heat transfer coefficients, whereas pressure drops can be substantially smaller than in typical convective boiling (Ohadi et al. 2013). The only limitation that has held this technology from being widely commercialized is the challenge of maintaining very thin films on the surface under wide-ranging operating conditions encountered in many systems. However, recent progress in microfabrication technologies, as well as measurement, instrumentation, and control of fluidic devices, may have substantially improved the prospect of commercially feasible thin-film evaporators. An important aspect of successful use of microchannels, for both single- and two-phase flow applications, is precise, evenly distributed liquid among the channels, which often requires careful design of liquid feed manifolds. Figure 11 depicts a schematic view of thin-film microchannels cooling over three-dimensional surfaces (Cetegen 2010).

Cetegen (2010) obtained critical heat flux in excess of 0.012 kW/mm^2, measured at average wall superheat of 56.2 K and subcooling of 8.5 K. The corresponding pressure drop was only 60.3 kPa, and a resulting pumping power of only 1.1 W. The heat sink footprint area tested in this study was 7.8 × 7.8 mm^2.

Mandel (2016) applied the force-fed microchannel heat sink (FFMHS) concept to a 10 × 10 mm^2 heat sink directly etched into a silicon die, achieving more than 1 kW/cm^2 at 85.6 K, 40% thermodynamic outlet vapor quality, and subcooling of 7.66 K. The corresponding pressure drop was only 87.3 kPa, and the resulting pumping power was only 0.79 W, approximately 43.5% less than Cetegen's results despite the 64% larger heat sink area. In addition, because the substrate material was silicon, temperature dropped significantly through the substrate, and the superheat at the base of the fins was estimated to be only 42.05 K.

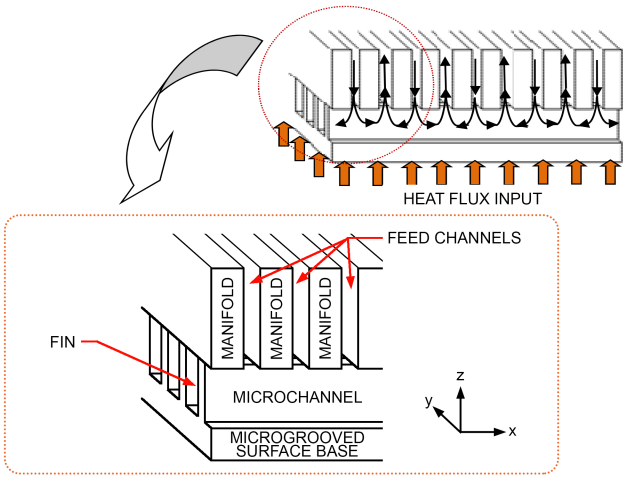

Fig. 11 Schematic Flow Representation of a Typical Force-Fed Microchannel Heat Sink (FFMHS)
(Cetegen 2010)

Licensed for single user. © 2021 ASHRAE, Inc.

Comparing cooling technologies for two-phase heat transfer is more challenging than for single phase, because heat sink performance depends on many more parameters. Nevertheless, a quantitative comparison can still be made by plotting the data over the two most important parameters: here, maximum heat flux and pumping power over cooling capacity ratio. For these parameters, the performance of force-fed heat transfer was compared with other competing high-heat-flux cooling technologies by Agostini et al. (2008), Kosar and Peles (2007), Sung and Mudawar (2009), and Visaria and Mudawar (2008); the resulting graph, compiled by Cetegen (2010), is shown in Figure 12.

In addition, thin-film-enhanced evaporation in microchannels has been extended to shell-and-tube heat exchangers for enhanced evaporation heat transfer. Jha et al. (2012) found more than fourfold enhancement of the heat exchanger's overall heat transfer coefficient U compared to a state-of-the-art plate heat exchanger for the same operating parametric ranges. Working fluids for this study were R-245fa and water, for shell and tube sides, respectively. The pressure drops/pumping power reported in this study were substantially below those of the conventional shell-and-tube, as well as respective plate evaporators. Equally impressive results were reported with condensation heat transfer in thin-film-enhanced microchannels. Additional detailed information can be found in Ohadi et al. (2013).

Force-fed microchannel heat exchangers have also been used to enhance condensation heat transfer. Boyea et al. (2013) developed and tested a compact, low-mass manifold microgroove condenser, with 60 × 600 µm microgrooves and cooling capacity of 4 kW using different manifolds. Experiments using R-236fa and R-134a as working fluids measured inlet and outlet temperatures, flow rates, and pressure drops for the refrigerant and water sides. Overall heat transfer coefficient and pressure drop across condenser were determined, and refrigerant-side heat transfer coefficient was calculated based on water-side heat transfer coefficient. Refrigerant-side heat transfer coefficient of 60 kW/(m^2·K) with pressure drop of just 7 kPa was demonstrated using R-134a. Experimental results indicate significant effect of manifold geometry on condenser performances. However, additional tests and verifications are needed to demonstrate the applicability of this technique for scaled-up, real-world condensers.

Kale and Mehendale (2015) critically assessed five microfin tube condensation correlations to determine their predictive accuracy and applicability for halogenated refrigerants and CO_2 in specific applications. This novel methodology was developed and validated against a dataset of 1163 experimental data points for CO_2, R-22, R-134a, R-410A, R-407C, R-125, and other halogenated refrigerants obtained from a large number of published works, which included diverse microfin tube geometries and condensing conditions. A similar study of the flow boiling HTC correlations was conducted by Merchant and Mehendale (2015).

Recent advancements in surface engineering offer new opportunities to enhance condensation heat transfer by drastically changing the wetting properties of the surface. Specifically, the development of superhydrophobic surfaces has been pursued to enhance dropwise condensation heat transfer, where the low droplet surface adhesion and small droplet departure sizes increase the condensation heat transfer coefficient. Figure 13 shows various microstructures of different sizes.

4. SYMBOLS

A = area, effective plate area
a = local acceleration
b = breadth of condensing surface. For vertical tube, $b = \pi d$; for horizontal tube, $b = 2L$; flow channel gap in flat plate heat exchanger.
Bo = boiling number = $q/(Gh_{fg})$
C = coefficient or constant

C_F = Fanning friction factor
Co = Shah's convection number = $(1/x - 1)^{0.8}(\rho_g/\rho_f)^{0.5}$
c_p = specific heat at constant pressure
c_v = specific heat at constant volume
D = diameter
D_o = outside tube diameter
d = diameter; or prefix meaning differential
(dp/dz) = pressure drop
$(dp/dz)_{fric}$ = frictional pressure drop
$(dp/dz)_l$ = frictional pressure drop, assuming that liquid alone is flowing in pipe
$(dp/dz)_{mom}$ = momentum pressure drop
$(dp/dz)_v$ = frictional pressure drop, assuming that gas (or vapor) alone is flowing in pipe
Fr = Froude number
Fr_l = Froude number for total mass flow rate (vapor + liquid) = $G^2/(\rho_f{}^2GD)$
f = friction factor for single-phase flow (Fanning)
G = total mass velocity (vapor + liquid); gravitational acceleration; mass flux
g_c = gravitational constant
Gr = Grashof number
h = heat transfer coefficient
h_f = single-phase liquid heat transfer coefficient
h_{fg} = latent heat of vaporization or of condensation
i'_{fg} = modified latent heat = $i_{fg}(1 + 0.68c_p\,\Delta T/i_{fg})$
j = Colburn j-factor
k = thermal conductivity
K_D = mass transfer coefficient, dimensionless coefficient (Table 1)
L = length
L_p = plate length
LT = total mass flowing as liquid
M = mass; or molecular weight
m = general exponent
$\dot{m}$ = mass flow rate
M_m = mean molecular weight of vapor/gas mixture
M_v = molecular weight of condensing vapor
N = number of tubes in vertical tier
n = general exponent
Nu = Nusselt number
P = pressure; or plate perimeter
p^* = reduced pressure (P/p_c)
p_c = critical thermodynamic pressure for coolant
p_g = partial pressure of noncondensable gas
Pr = Prandtl number
p_r = reduced pressure = p/p_c
p_v = partial pressure of vapor
Q_v = volumetric flow rate
q, q'' = heat flux
r = radius
Ra = Rayleigh number
Re = Reynolds number
R_p = surface roughness, µm
T, t = temperature
U = overall heat transfer coefficient
V = linear velocity
We = Weber number
x = quality (i.e., mass fraction of vapor); or distance in dt/dx
X_{tt} = Martinelli parameter
x, y, z = lengths along principal coordinate axes
Y_g = mole fraction of noncondensable gas
Y_v = mole fraction of vapor
Z = Shah parameter = $(1/x - 1)^{0.8}p_r{}^{0.4}$

Greek

α = thermal diffusivity = $k/\rho c_p$
β = coefficient of thermal expansion, chevron angle
β^* = chevron angle ratio (β/β_{min})
Γ = mass rate of flow of condensate per unit of breadth (see section on Condensing)
Δ = difference between values

CHAPTER 6

MASS TRANSFER

Molecular Diffusion 6.1
Convection of Mass 6.5
Simultaneous Heat and Mass Transfer Between Water-Wetted Surfaces and Air 6.10
Symbols 6.14

Licensed for single user. © 2021, ASHRAE, Inc.

MASS transfer by either molecular diffusion or convection is the transport of one component of a mixture relative to the motion of the mixture and is the result of a **concentration gradient**. Mass transfer can occur in liquids and solids as well as gases. For example, water on the wetted slats of a cooling tower evaporates into air in a cooling tower (liquid-to-gas mass transfer), and water vapor from a food product transfers to the dry air as it dries. A piece of solid CO_2 (dry ice) also gets smaller and smaller over time as the CO_2 molecules diffuse into air (solid-to-gas mass transfer). A piece of sugar added to a cup of coffee eventually dissolves and diffuses into the solution, sweetening the coffee, although the sugar molecules are much heavier than the water molecules (solid-to-liquid mass transfer). Air freshener does not just smell where sprayed, but rather the smell spreads throughout the room. The air freshener (matter) moves from an area of high concentration where sprayed to an area of low concentration far away. In an absorption chiller, low-pressure, low-temperature refrigerant vapor from the evaporator enters the thermal compressor in the absorber section, where the refrigerant vapor is absorbed by the strong absorbent (concentrated solution) and dilutes the solution.

In air conditioning, water vapor is added or removed from the air by simultaneous transfer of heat and mass (water vapor) between the airstream and a wetted surface. The wetted surface can be water droplets in an air washer, condensate on the surface of a dehumidifying coil, a spray of liquid absorbent, or wetted surfaces of an evaporative condenser. Equipment performance with these phenomena must be calculated carefully because of simultaneous heat and mass transfer.

This chapter addresses mass transfer principles and provides methods of solving a simultaneous heat and mass transfer problem involving air and water vapor, emphasizing air-conditioning processes. The formulations presented can help analyze performance of specific equipment. For discussion of performance of cooling coils, evaporative condensers, cooling towers, and air washers, see Chapters 23, 39, 40, and 41, respectively, of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

1. MOLECULAR DIFFUSION

Most mass transfer problems can be analyzed by considering diffusion of a gas into a second gas, a liquid, or a solid. In this chapter, the diffusing or dilute component is designated as component B, and the other component as component A. For example, when water vapor diffuses into air, the water vapor is component B and dry air is component A. Properties with subscripts A or B are local properties of that component. Properties without subscripts are local properties of the mixture.

The primary mechanism of mass diffusion at ordinary temperature and pressure conditions is **molecular diffusion**, a result of density gradient. In a binary gas mixture, the presence of a concentration gradient causes transport of matter by molecular diffusion; that is, because of random molecular motion, gas B diffuses through the mixture of gases A and B in a direction that reduces the concentration gradient.

Fick's Law

The basic equation for molecular diffusion is Fick's law. Expressing the concentration of component B of a binary mixture of components A and B in terms of the mass fraction ρ_B/ρ or mole fraction C_B/C, Fick's law is

$$J_B = -\rho D_v \frac{d(\rho_B/\rho)}{dy} = -J_A \tag{1a}$$

$$J_B^* = -CD_v \frac{d(C_B/C)}{dy} = -J_A^* \tag{1b}$$

where $\rho = \rho_A + \rho_B$ and $C = C_A + C_B$.

The minus sign indicates that the concentration gradient is negative in the direction of diffusion. The proportionality factor D_v is the **mass diffusivity** or the **diffusion coefficient**. The total mass flux $\dot{m}_B''$ and molar flux $m_B''^*$ are due to the average velocity of the mixture plus the diffusive flux:

$$\dot{m}_B'' = \rho_B v - \rho D_v \frac{d(\rho_B/\rho)}{dy} \tag{2a}$$

$$m_B''^* = C_B v^* - CD_v \frac{d(C_B/C)}{dy} \tag{2b}$$

where v is the mixture's mass average velocity and v^* is the molar average velocity.

Bird et al. (1960) present an analysis of Equations (1a) and (1b). Equations (1a) and (1b) are equivalent forms of Fick's law. The equation used depends on the problem and individual preference. This chapter emphasizes mass analysis rather than molar analysis. However, all results can be converted to the molar form using the relation $C_B \equiv \rho_B/M_B$.

Fick's Law for Dilute Mixtures

In many mass diffusion problems, component B is dilute, with a density much smaller than the mixture's. In this case, Equation (1a) can be written as

$$J_B = -D_v \frac{d\rho_B}{dy} \tag{3}$$

when $\rho_B << \rho$ and $\rho_A \approx \rho$.

Equation (3) can be used without significant error for water vapor diffusing through air at atmospheric pressure and a temperature less than 27°C. In this case, $\rho_B < 0.02\rho$, where ρ_B is the density of water vapor and ρ is the density of moist air (air and water vapor mixture). The error in J_B caused by replacing $\rho[d(\rho_B/\rho)/dy]$ with $d\rho_B/dy$ is less than 2%. At temperatures below 60°C where $\rho_B < 0.10\rho$, Equation (3) can still be used if errors in J_B as great as 10% are tolerable.

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

Fick's Law for Mass Diffusion Through Solids or Stagnant Fluids (Stationary Media)

Fick's law can be simplified for cases of dilute mass diffusion in solids, stagnant liquids, or stagnant gases. In these cases, $\rho_B << \rho$ and $v \approx 0$, which yields the following approximate result:

$$\dot{m}''_B = J_B = -D_v \frac{d\rho_B}{dy} \tag{4}$$

Fick's Law for Ideal Gases with Negligible Temperature Gradient

For dilute mass diffusion, Fick's law can be written in terms of partial pressure gradient instead of concentration gradient. When gas B can be approximated as ideal,

$$p_B = \frac{\rho_B R_u T}{M_B} = C_B R_u T \tag{5}$$

and when the gradient in T is small, Equation (3) can be written as

$$J_B = -\left(\frac{M_B D_v}{R_u T}\right)\frac{dp_B}{dy} \tag{6a}$$

or

$$J^*_B = -\left(\frac{D_v}{R_u T}\right)\frac{dp_B}{dy} \tag{6b}$$

If $v \approx 0$, Equation (4) may be written as

$$\dot{m}''_B = J_B = -\left(\frac{M_B D_v}{R_u T}\right)\frac{dp_B}{dy} \tag{7a}$$

or

$$m''^*_B = J^*_B = -\left(\frac{D_v}{R_u T}\right)\frac{dp_B}{dy} \tag{7b}$$

The partial pressure gradient formulation for mass transfer analysis has been used extensively; this is unfortunate because the pressure formulation [Equations (6) and (7)] applies only when one component is dilute, the fluid closely approximates an ideal gas, and the temperature gradient has a negligible effect. The density (or concentration) gradient formulation expressed in Equations (1) to (4) is more general and can be applied to a wider range of mass transfer problems, including cases where neither component is dilute [Equation (1)]. The gases need not be ideal, nor the temperature gradient negligible. Consequently, this chapter emphasizes the density formulation.

Diffusion Coefficient

For a binary mixture, the diffusion coefficient D_v is a function of temperature, pressure, and composition. Experimental measurements of D_v for most binary mixtures are limited in range and accuracy. Table 1 gives a few experimental values for diffusion of some gases in air. For more detailed tables, see the Bibliography.

Table 1 Mass Diffusivities for Gases in Air*

Gas	D_v, mm²/s
Ammonia	27.9
Benzene	8.8
Carbon dioxide	16.5
Ethanol	11.9
Hydrogen	41.3
Oxygen	20.6
Water vapor	25.5

*Gases at 25°C and 101.325 kPa.

In the absence of data, use equations developed from (1) theory or (2) theory with constants adjusted from limited experimental data. For binary gas mixtures at low pressure, D_v is inversely proportional to pressure, increases with increasing temperature, and is almost independent of composition for a given gas pair. Bird et al. (1960) present the following equation, developed from kinetic theory and corresponding states arguments, for estimating D_v at pressures less than $0.1p_{c\,min}$:

$$D_v = a\left(\frac{T}{\sqrt{T_{cA}T_{cB}}}\right)^b \sqrt{\frac{1}{M_A}+\frac{1}{M_B}} \times \frac{(p_{cA}p_{cB})^{1/3}(T_{cA}T_{cB})^{5/12}}{p} \tag{8}$$

where

D_v = diffusion coefficient, mm²/s
a = constant that depends on units used
b = constant, dimensionless
T = absolute temperature, K
p = pressure, kPa
M = relative molecular mass, kg/kg mol

Subscripts cA and cB refer to the critical states of the two gases. Analysis of experimental data gives the following values of the constants a and b:

For nonpolar gas pairs

$$a = 0.1280 \quad \text{and} \quad b = 1.823$$

For water vapor with a nonpolar gas

$$a = 0.1697 \quad \text{and} \quad b = 2.334$$

In **nonpolar gas**, intermolecular forces are independent of the relative orientation of molecules, depending only on the separation distance from each other. Air, composed almost entirely of nonpolar gases O_2 and N_2, is nonpolar.

Equation (8) is stated to agree with experimental data at atmospheric pressure to within about 8% (Bird et al. 1960).

Mass diffusivity D_v for binary mixtures at low pressure is predictable within about 10% by kinetic theory (Reid et al. 1987).

$$D_v = 0.1881\frac{T^{1.5}}{p(\sigma_{AB})^2\Omega_{D,AB}}\sqrt{\frac{1}{M_A}+\frac{1}{M_B}} \tag{9}$$

where

σ_{AB} = characteristic molecular diameter, nm
$\Omega_{D,AB}$ = temperature function, dimensionless

D_v is in mm²/s, p in kPa, and T in K. If the gas molecules of A and B are considered rigid spheres having diameters σ_A and σ_B [and $\sigma_{AB} = (\sigma_A/2) + (\sigma_B/2)$], all expressed in nanometres, the dimensionless function $\Omega_{D,AB}$ equals unity. More realistic models for molecules having intermolecular forces of attraction and repulsion lead to values that are functions of temperature. Bird et al. (1960) and Reid et al. (1987) present tabulations of $\Omega_{D,AB}$. These results show that D_v increases as the 2.0 power of T at low temperatures and as the 1.65 power of T at very high temperatures.

The diffusion coefficient of moist air has been calculated for Equation (8) using a simplified intermolecular potential field function for water vapor and air (Mason and Monchick 1965). The following empirical equation is for mass diffusivity of water vapor in air up to 1100°C (Sherwood and Pigford 1952):

$$D_v = \frac{0.926}{p}\left(\frac{T^{2.5}}{T+245}\right) \tag{10}$$

Licensed for single user. © 2021, ASHRAE, Inc.

Example 1. Evaluate the diffusion coefficient of CO_2 in air at 293 K and atmospheric pressure (101.325 kPa) using Equation (9).

Solution: In Equation (9), D_v is in mm^2/s, $\sigma_{AB} = (\sigma_A/2) + (\sigma_B/2)$, and the Lennard-Jones energy parameter $\varepsilon_{AB}/k = \sqrt{(\varepsilon_A/k)(\varepsilon_B/k)}$. Values of σ and ε for each gas are as follows:

	σ, nm	ε/*k*, K
CO_2	0.3996	190
Air	0.3617	97

The combined values for use in Equation (9) are

$$\sigma_{AB} = 0.3996/2 + 0.3617/2 = 0.3806 \text{ nm}$$

$$\varepsilon_{AB}/k = \sqrt{(190)(97)} = 136 \text{ at } P = 101.325 \text{ kPa and } T = 293 \text{ K}$$

$$\frac{\varepsilon_{AB}}{kT} = \frac{136}{293} = 0.463 \qquad \frac{kT}{\varepsilon_{AB}} = \frac{1}{0.463} = 2.16$$

From tables for $\Omega_{D,AB}$ at $kT/\varepsilon_{AB} = 2.16$ (Bird et al. 1960; Reid et al. 1987), the collision integral $\Omega_{D,AB} = 1.047$. The relative molecular masses of CO_2 and air are 44 and 29, respectively. Substituting these values gives

$$D_v = 0.1881[293^{1.5}/(101.325 \times 0.3806^2 \times 1.047)](1/44 + 1/29)^{0.5}$$
$$= 14.68 \text{ mm}^2/\text{s}$$

Diffusion of One Gas Through a Second Stagnant Gas

Figure 1 shows diffusion of one gas through a second, stagnant gas. Water vapor diffuses from the liquid surface into surrounding stationary air. It is assumed that local equilibrium exists through the gas mixture, that the gases are ideal, and that the Gibbs-Dalton law is valid, which implies that temperature gradient has a negligible effect. Water vapor diffuses because of concentration gradient, as given by Equation (6a). There is a continuous gas phase, so the mixture pressure p is constant, and the Gibbs-Dalton law yields

$$p_A + p_B = p = \text{constant} \tag{11a}$$

or

$$\frac{\rho_A}{M_A} + \frac{\rho_B}{M_B} = \frac{p}{R_u T} = \text{constant} \tag{11b}$$

The partial pressure gradient of the water vapor causes a partial pressure gradient of the air such that

$$\frac{dp_A}{dy} = -\frac{dp_B}{dy} \tag{11c}$$

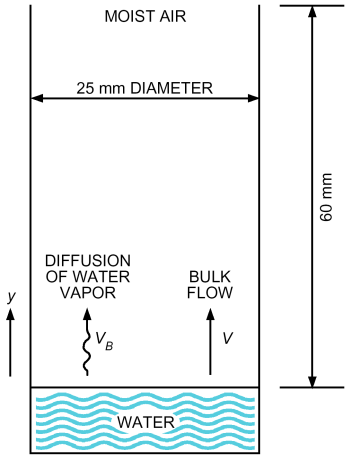

Fig. 1 Diffusion of Water Vapor Through Stagnant Air

or

$$\left(\frac{1}{M_A}\right)\frac{d\rho_A}{dy} = -\left(\frac{1}{M_B}\right)\frac{d\rho_B}{dy} \tag{12}$$

Air, then, diffuses toward the liquid water interface. Because it cannot be absorbed there, a bulk velocity v of the gas mixture is established in a direction away from the liquid surface, so that the net transport of air is zero (i.e., the air is stagnant):

$$\dot{m}''_A = -D_v \frac{d\rho_A}{dy} + \rho_A v = 0 \tag{13}$$

The bulk velocity v transports not only air but also water vapor away from the interface. Therefore, the total rate of water vapor diffusion is

$$\dot{m}''_B = -D_v \frac{d\rho_B}{dy} + \rho_B v \tag{14}$$

Substituting for the velocity v from Equation (13) and using Equations (11b) and (12) gives

$$\dot{m}''_B = \left(\frac{D_v M_B p}{\rho_A R_u T}\right)\frac{d\rho_A}{dy} \tag{15}$$

Integration yields

$$\dot{m}''_B = \frac{D_v M_B p}{R_u T}\left[\frac{\ln(\rho_{AL}/\rho_{A0})}{y_L - y_0}\right] \tag{16a}$$

or

$$\dot{m}''_B = -D_v P_{Am}\left(\frac{\rho_{BL} - \rho_{B0}}{y_L - y_0}\right) \tag{16b}$$

where

$$P_{Am} \equiv \frac{p}{p_{AL}}\rho_{AL}\left[\frac{\ln(\rho_{AL}/\rho_{A0})}{\rho_{AL} - \rho_{A0}}\right] \tag{17}$$

P_{Am} is the logarithmic mean density factor of the stagnant air. The pressure distribution for this type of diffusion is shown in Figure 2. **Stagnant** refers to the net behavior of the air; it does not move because bulk flow exactly offsets diffusion. The term P_{Am} in Equation (16b) approximately equals unity for dilute mixtures such as water vapor in air at near-atmospheric conditions. This condition makes it possible to simplify Equations (16) and implies that, for dilute mixtures, the partial pressure distribution curves in Figure 2 are straight lines.

Example 2. A vertical tube of 25 mm diameter is partially filled with water so that the distance from the water surface to the open end of the tube is 60 mm, as shown in Figure 1. Perfectly dried air is blown over the open tube end, and the complete system is at a constant temperature of 15°C. In 200 h of steady operation, 2.15 g of water evaporates from the tube. The total pressure of the system is 101.325 kPa. Using these data, (1) calculate the mass diffusivity of water vapor in air, and (2) compare this experimental result with that from Equation (10).

Solution:

(1) The mass diffusion flux of water vapor from the water surface is

$$\dot{m}_B = 2.15/200 = 0.01075 \text{ g/h}$$

The cross-sectional area of a 25 mm diameter tube is $\pi(12.5)^2 = 491$ mm^2. Therefore, $\dot{m}''_B = 0.00608$ g/(m^2·s). The partial densities are determined from psychrometric tables.

$$\rho_{BL} = 0; \quad \rho_{B0} = 12.8 \text{ g/m}^3$$

$$\rho_{AL} = 1.225 \text{ kg/m}^3; \quad \rho_{A0} = 1.204 \text{ kg/m}^3$$

Licensed for single user. © 2021, ASHRAE, Inc.

Because $p = p_{AL} = 101.325$ kPa, the logarithmic mean density factor [Equation (17)] is

$$P_{Am} = 1.225\left[\frac{\ln(1.225/1.204)}{1.225-1.204}\right] = 1.009$$

The mass diffusivity is now computed from Equation (16b) as

$$D_v = \frac{-\dot{m}''_B(y_L - y_0)}{P_{Am}(\rho_{BL} - \rho_{B0})} = \frac{-(0.00608)(0.060)(10^6)}{(1.009)(0-12.8)}$$

$$= 28.2 \text{ mm}^2/\text{s}$$

(2) By Equation (10), with $p = 101.325$ kPa and $T = 15 + 273 = 288$ K,

$$D_v = \frac{0.926}{101.325}\left(\frac{288^{2.5}}{288+245}\right) = 24.1 \text{ mm}^2/\text{s}$$

Neglecting the correction factor P_{Am} for this example gives a difference of less than 1% between the calculated experimental and empirically predicted values of D_v.

Equimolar Counterdiffusion

Figure 3 shows two large chambers, both containing an ideal gas mixture of two components A and B (e.g., air and water vapor) at the same total pressure p and temperature T. The two chambers are connected by a duct of length L and cross-sectional area A_{cs}. Partial pressure p_B is higher in the left chamber, and partial pressure p_A is higher in the right chamber. The partial pressure differences cause component B to migrate to the right and component A to migrate to the left.

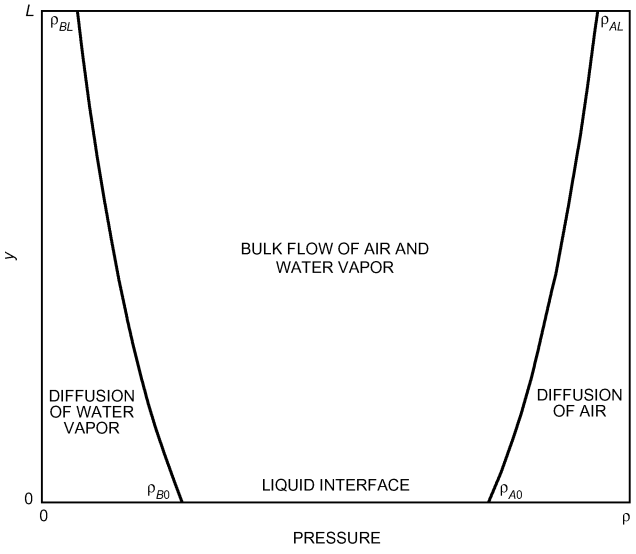

Fig. 2 Pressure Profiles for Diffusion of Water Vapor Through Stagnant Air

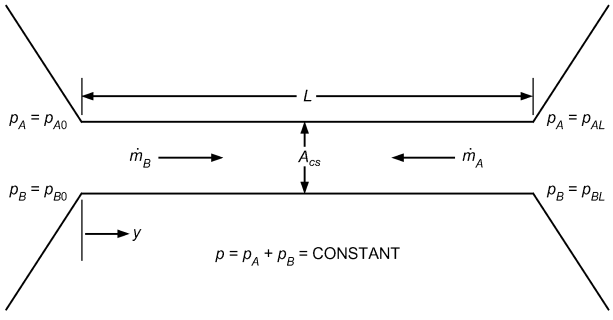

Fig. 3 Equimolar Counterdiffusion

At steady state, the molar flows of A and B must be equal but opposite:

$$\dot{m}''^*_A + \dot{m}''^*_B = 0 \tag{18}$$

because the total molar concentration C must stay the same in both chambers if p and T remain constant. Because molar fluxes are the same in both directions, the molar average velocity $v^* = 0$. Thus, Equation (7b) can be used to calculate the molar flux of B (or A):

$$\dot{m}''^*_B = \frac{-D_v}{R_u T}\frac{dp_B}{dy} \tag{19}$$

or

$$\dot{m}^*_B = \frac{A_{cs}D_v}{R_u T}\left(\frac{p_{B0}-p_{BL}}{L}\right) \tag{20}$$

or

$$\dot{m}_B = \frac{M_B A_{cs} D_v}{R_u T}\left(\frac{p_{B0}-p_{BL}}{L}\right) \tag{21}$$

Example 3. One large room is maintained at 22°C (295 K), 101.3 kPa, 80% rh. A 20 m long duct with cross-sectional area of 0.15 m^2 connects the room to another large room at 22°C, 101.3 kPa, 10% rh. What is the rate of water vapor diffusion between the two rooms?

Solution: Let air be component A and water vapor be component B. Equation (21) can be used to calculate the mass flow of water vapor B. Equation (10) can be used to calculate the diffusivity.

$$D_v = \frac{0.926}{101.3}\left(\frac{295^{2.5}}{295+245}\right) = 25.3 \text{ mm}^2/\text{h}$$

From a psychrometric table (Table 3, Chapter 1), the saturated vapor pressure at 22°C is 2.645 kPa. The vapor pressure difference $p_{B0} - p_{BL}$ is

$$p_{B0} - p_{BL} = (0.8 - 0.1)2.645 \text{ kPa} = 1.85 \text{ kPa}$$

Then, Equation (21) gives

$$\dot{m}_b = \frac{18 \times 0.15(25.3/10^6)}{8.314 \times 295}\frac{1.85}{20} = 2.58 \times 10^{-9} \text{ kg/s}$$

Molecular Diffusion in Liquids and Solids

Because of the greater density, diffusion is slower in liquids than in gases. No satisfactory molecular theories have been developed for calculating diffusion coefficients. The limited measured values of D_v show that, unlike for gas mixtures at low pressures, the diffusion coefficient for liquids varies appreciably with concentration.

Reasoning largely from analogy to the case of one-dimensional diffusion in gases and using Fick's law as expressed by Equation (4) gives

$$\dot{m}''_B = D_v\left(\frac{\rho_{B1}-\rho_{B2}}{y_2-y_1}\right) \tag{22}$$

Equation (22) expresses steady-state diffusion of solute B through solvent A in terms of the molal concentration difference of the solute at two locations separated by the distance $\Delta y = y_2 - y_1$. Bird et al. (1960), Eckert and Drake (1972), Hirschfelder et al. (1954), Reid and Sherwood (1966), Sherwood and Pigford (1952), and Treybal (1980) provide equations and tables for evaluating D_v. Hirschfelder et al. (1954) provide comprehensive treatment of the molecular developments.

Licensed for single user. © 2021, ASHRAE, Inc.

Diffusion through a solid when the solute is dissolved to form a homogeneous solid solution is known as **structure-insensitive diffusion** (Treybal 1980). This solid diffusion closely parallels diffusion through fluids, and Equation (22) can be applied to one-dimensional steady-state problems. Values of mass diffusivity are generally lower than they are for liquids and vary with temperature.

Diffusion of a gas mixture through a porous medium is common (e.g., diffusion of an air/vapor mixture through porous insulation or other vapor-permeable building materials). Vapor diffuses through the air along the tortuous narrow passages within the porous medium. Mass flux is a function of the vapor pressure gradient and diffusion coefficient, as indicated in Equation (7a). It is also a function of the structure of the pathways within the porous medium and is therefore called **structure-sensitive diffusion**. All these factors are taken into account in the following version of Equation (7a):

$$m''_B = -\bar{\mu}\frac{dp_B}{dy} \tag{23}$$

where $\bar{\mu}$ is called the moisture permeability of the porous medium. For a layer of porous solid L thick, $\bar{\mu}/L$ is called the permeance, the unit for which is kg/(s·m²·Pa). Permeance is also known as **vapor flow conductance**, which is analogous to heat flow conductance in heat transfer. **Permeability** is the product of permeance and layer thickness [i.e., kg/(s·m·Pa)], but is often given in units of ng/(s·m·Pa).

Consider a slab $L = y_2 - y_1$ thick with cross-sectional area A_c. The vapor pressure is p_{B1} on one side of the slab and p_{B2} on the other side. If the permeability $\bar{\mu}$ is constant, integration of Equation (23) yields

$$p_B(y) = p_{B1} - \frac{y - y_1}{L}(p_{B1} - p_{B2}) \tag{24}$$

$$m''_B = \frac{m_B}{A_c} = \bar{\mu}\frac{p_{B1} - p_{B2}}{L} \text{ or}$$

$$m_B = \frac{p_{B1} - p_{B2}}{L/(\bar{\mu}A_c)} \tag{25}$$

where m_B is the vapor flow rate. In Equation (25), $p_{B1} - p_{B2}$ can be considered a driving potential, and $L/(\bar{\mu}A_c)$ a resistance. This is analogous to Equation (1) in Chapter 4, where q is the heat transfer rate, $t_{s1} - t_{s2}$ is the driving potential, and $L/(kA_c)$ is the resistance.

Chapters 25 and 26 present this topic in more depth.

Example 4. A three-layer composite wall consisting of glass fiber batt insulation, a concrete block (limestone aggregate, 2240 kg/m³ concrete, with two perlite-filled cores) and brick (1920 kg/m³) is shown in Figure 4. The dry-bulb temperature and indoor dew point are T_i = 22°C and $T_{i,dp}$ = 7.2°C, respectively. Outdoor temperature T_o = –12°C, and relative humidity rh_o = 50%. The outdoor wind speed is 25 km/h.

(a) Calculate heat transfer rate through the wall (in W) per square metre of wall area.

(b) Calculate vapor flow rate through the wall (in g/h) per square metre of wall area.

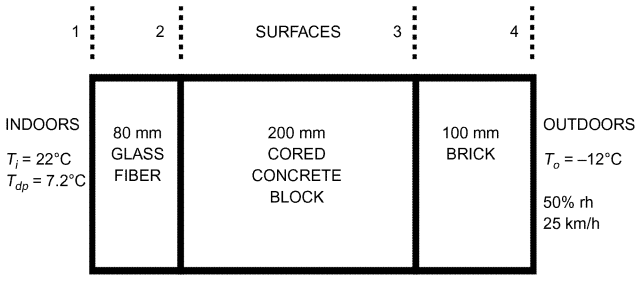

Fig. 4 Composite Wall for Example 4

Solution

Find (1) thermal conductivity k from Table 1 in Chapter 26; (2) film resistance coefficient $1/h$, where h is convective heat transfer coefficient, from Table 10 in Chapter 26; and (3) water vapor permeability $\bar{\mu}$ from Table 6 in Chapter 26. Calculate thermal resistance $L/(kA_c)$ and diffusion resistance $L/(\bar{\mu}A_c)$, for each layer. Calculate the film thermal resistance $1/(hA_s)$ at both surfaces. $A_s = A_c = 1$ m² because rates per square metre of wall area are required. Determine total thermal resistance R_T and total diffusion resistance r_T. See Table 2 for values.

(a) Calculate heat transmission through the wall.

$$q = \frac{(T_i - T_o)}{R_T} = \frac{(22 - [-12]°\text{C})}{2.966 \text{ K/W}} = 11.46 \text{ W or } \frac{q}{A_c} = 11.46 \text{ W/m}^2$$

(b) Calculate vapor flow rate through the wall. At T_i = 22°C and $T_{i,dp}$ = 7.2°C, vapor pressure p_{vi} = 1016 Pa. At T_o = –12°C and rh_o = 50%, p_{vo} = 122 Pa. The vapor flow rate is then

$$m_v = \frac{(p_{v,i} - p_{v,o})}{r_T} = \frac{(1016 - 122) \text{ Pa}}{0.02727 \text{ (s·Pa)/ng}} = 32\,783 \text{ ng/s}$$

$$= 0.1184 \text{ g/h or } \frac{m_v}{A_c} = 0.1184 \text{ g/(h·m}^2\text{)}$$

$$m_v = \frac{(p_{v,i} - p_{v,o})}{r_T} = \frac{(1016 - 122) \text{ Pa}}{0.02719 \text{ (s·Pa)/ng}} = 32\,879 \text{ ng/s}$$

$$= 0.1184 \text{ g/h or } \frac{m_v}{A_c} = 0.1184 \text{ g/(h·m}^2\text{)}$$

2. CONVECTION OF MASS

Convection of mass involves the mass transfer mechanisms of molecular diffusion and bulk fluid motion. Fluid motion in the region adjacent to a mass transfer surface may be laminar or turbulent, depending on geometry and flow conditions.

Mass Transfer Coefficient

Convective mass transfer is analogous to convective heat transfer where geometry and boundary conditions are similar. The analogy holds for both laminar and turbulent flows and applies to both external and internal flow problems.

Mass Transfer Coefficients for External Flows. Most external convective mass transfer problems can be solved with an appropriate formulation that relates the mass transfer flux (to or from an interfacial surface) to the concentration difference across the boundary layer illustrated in Figure 5. This formulation gives rise to the convective mass transfer coefficient, defined as

$$h_M \equiv \frac{m''_B}{\rho_{Bi} - \rho_{B\infty}} \tag{26}$$

where

h_M = local external mass transfer coefficient, m/s
m''_B = mass flux of gas B from surface, kg/(m²·s)
ρ_{Bi} = density of gas B at interface (saturation density), kg/m³
$\rho_{B\infty}$ = density of component B outside boundary layer, kg/m³

If ρ_{Bi} and $\rho_{B\infty}$ are constant over the entire interfacial surface, the mass transfer rate from the surface can be expressed as

$$m''_B = \bar{h}_M(\rho_{Bi} - \rho_{B\infty}) \tag{27}$$

where $\bar{h}_M$ is the average mass transfer coefficient, defined as

$$\bar{h}_M \equiv \frac{1}{A}\int_A h_m \, dA \tag{28}$$

Mass Transfer Coefficients for Internal Flows. Most internal convective mass transfer problems, such as those that occur in chan-

nels or in the cores of dehumidification coils, can be solved if an appropriate expression is available to relate the mass transfer flux (to or from the interfacial surface) to the difference between the concentration at the surface and the bulk concentration in the channel, as shown in Figure 6. This formulation leads to the definition of the mass transfer coefficient for internal flows:

$$h_M \equiv \frac{m''_B}{\rho_{Bi} - \rho_{Bb}} \tag{29}$$

where

h_M = internal mass transfer coefficient, m/s
m''_B = mass flux of gas B at interfacial surface, kg/(m²·s)
ρ_{Bi} = density of gas B at interfacial surface, kg/m³
$\rho_{Bb} \equiv (1/\bar{u}_B A_{cs}) \int_{A_{cs}} u_B \rho_B \, dA_{cs}$ = bulk density of gas B at location x
$\bar{u}_B \equiv (1/A_{cs}) \int_A u_B \, dA_{cs}$ = average velocity of gas B at location x, m/s
A_{cs} = cross-sectional area of channel at station x, m²
u_B = velocity of component B in x direction, m/s
ρ_B = density distribution of component B at station x, kg/m³

Often, it is easier to obtain the bulk density of gas B from

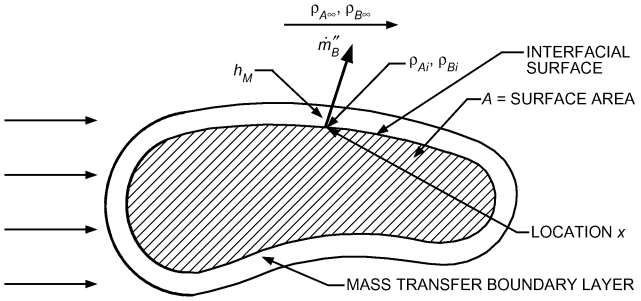

Fig. 5 Nomenclature for Convective Mass Transfer from External Surface at Location x Where Surface Is Impermeable to Gas A

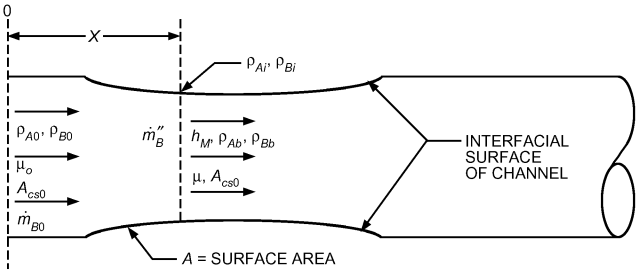

Fig. 6 Nomenclature for Convective Mass Transfer from Internal Surface Impermeable to Gas A

$$\rho_{Bb} = \frac{\dot{m}_{Bo} + \int_A m''_B dA}{\bar{u}_B A_{cs}} \tag{30}$$

where

$\dot{m}_{Bo}$ = mass flow rate of component B at station $x = 0$, kg/s
A = interfacial area of channel between station $x = 0$ and station $x = x$, m²

Equation (28) can be derived from the preceding definitions. The major problem is determining $\bar{u}_B$. If, however, analysis is restricted to cases where B is dilute and concentration gradients of B in the x direction are negligibly small, $\bar{u}_B \approx \bar{u}$. Component B is swept along in the x direction with an average velocity equal to the average velocity of the dilute mixture.

Analogy Between Convective Heat and Mass Transfer

Most expressions for the convective mass transfer coefficient h_M are determined from expressions for the convective heat transfer coefficient h.

For problems in internal and external flow where mass transfer occurs at the convective surface and where component B is dilute, Bird et al. (1960) and Incropera and DeWitt (1996) found that the Nusselt and Sherwood numbers are defined as follows:

$$\text{Nu} = f(X, Y, Z, \text{Pr}, \text{Re}) \tag{31}$$

$$\text{Sh} = f(X, Y, Z, \text{Sc}, \text{Re}) \tag{32}$$

and

$$\overline{\text{Nu}} = g(\text{Pr}, \text{Re}) \tag{33}$$

$$\overline{\text{Sh}} = g(\text{Sc}, \text{Re}) \tag{34}$$

where f in Equations (31) and (32) indicates a functional relationship among the dimensionless groups shown. The function f is the same in both equations. Similarly, g indicates a functional relationship that is the same in Equations (33) and (34). Pr and Sc are dimensionless Prandtl and Schmidt numbers, respectively, as defined in the Symbols section. The primary restrictions on the analogy are that the surface shapes are the same and that the temperature boundary conditions are analogous to the density distribution boundary conditions for component B when cast in dimensionless form. Several primary factors prevent the analogy from being perfect. In some cases, the Nusselt number was derived for smooth surfaces. Many mass transfer problems involve wavy, droplet-like, or roughened surfaces. Many Nusselt number relations are obtained for constant-temperature surfaces. Sometimes ρ_{Bi} is not constant over the entire surface because of varying saturation conditions and the possibility of surface dryout.

In all mass transfer problems, there is some blowing or suction at the surface because of condensation, evaporation, or transpiration of component B. In most cases, this blowing/suction has little effect on the Sherwood number, but the analogy should be examined closely if $v_i/u_\infty > 0.01$ or $v_i/\bar{u} > 0.01$, especially if the Reynolds number is large.

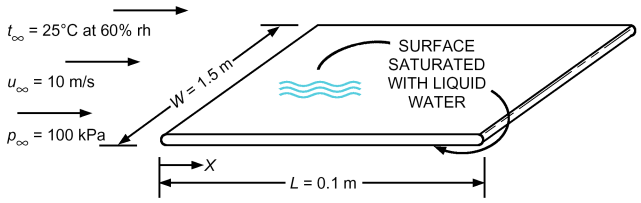

Fig. 7 Water-Saturated Flat Plate in Flowing Airstream

Example 5. Air at 25°C, 100 kPa, and 60% rh flows at 10 m/s, as shown in Figure 7. Find the rate of evaporation, rate of heat transfer to the water, and water surface temperature.

Solution: Heat transfer to water from air supplies the energy required to evaporate the water.

$$q = hA(t_\infty - t_s) = \dot{m} h_{fg} = h_M A(\rho_s - \rho_\infty) h_{fg}$$

where

h = convective heat transfer coefficient
h_M = convective mass transfer coefficient
A = $0.1 \times 1.5 \times 2 = 0.3$ m^2 = surface area (both sides)
$\dot{m}$ = evaporation rate
t_s, ρ_s = temperature and vapor density at water surface
t_∞, ρ_∞ = temperature and vapor density of airstream

This energy balance can be rearranged to give

$$\rho_s - \rho_\infty = \frac{h}{h_M}\left[\frac{(t_\infty - t_s)}{h_{fg}}\right]$$

The heat transfer coefficient h is found by first calculating the Nusselt number:

$$\text{Nu} = 0.664\,\text{Re}^{1/2}\text{Pr}^{1/3} \quad \text{for laminar flow}$$
$$\text{Nu} = 0.037\,\text{Re}^{4/5}\text{Pr}^{1/3} \quad \text{for turbulent flow}$$

The mass transfer coefficient h_M requires calculation of Sherwood number Sh, obtained using the analogy expressed in Equations (33) and (34):

$$\text{Sh} = 0.664\,\text{Re}^{1/2}\text{Pr}^{1/3} \quad \text{for laminar flow}$$
$$\text{Sh} = 0.037\,\text{Re}^{4/5}\text{Pr}^{1/3} \quad \text{for turbulent flow}$$

With Nu and Sh known,

$$h_M = \frac{\text{Sh}\,D_v}{L} \qquad h = \frac{\text{Nu}\,k}{L}$$

or

$$\frac{h}{h_M} = \frac{\text{Nu}\,k}{\text{Sh}\,D_v} = \left(\frac{\text{Pr}}{\text{Sc}}\right)^{1/3}\frac{k}{D_v}$$

This result is valid for both laminar and turbulent flow. Using this result in the preceding energy balance gives

$$\rho_s - \rho_\infty = \left(\frac{\text{Pr}}{\text{Sc}}\right)^{1/3}\frac{k}{D_v}\left[\frac{(t_\infty - t_s)}{h_{fg}}\right]$$

This equation must be solved for ρ_s. Then, water surface temperature t_s is the saturation temperature corresponding to ρ_s. Air properties Sc, Pr, D_v, and k are evaluated at film temperature $t_f = (t_\infty + t_s)/2$, and h_{fg} is evaluated at t_s. Because t_s appears in the right side and all the air properties also vary somewhat with t_s, iteration is required. Start by guessing t_s = 14°C (the dew point of the airstream), giving t_f = 19.5°C. At these temperatures, values on the right side are found in property tables or calculated as

k = 0.0257 W/(m·K)
Pr = 0.709
D_v = 2.521×10^{-5} m^2/s [from Equation (10)]
ρ = 1.191 kg/m^3
μ = 1.809×10^{-5} kg/(m·s)
Sc = $\mu/\rho D_v$ = 0.6025
h_{fg} = 2.455×10^6 J/kg (at 14°C)
ρ_∞ = 0.01417 kg/m^3 (from psychrometric chart at 25°C, 60% rh)
t_s = 14°C (initial guess)

Solving yields ρ_s = 0.01896 kg/m^3. The corresponding value of t_s = 21.6°C. Repeat the process using t_s = 21.6°C as the initial guess. The result is ρ_s = 0.01565 kg/m^3 and t_s = 18.3°C. Continue iterations until ρ_s converges to 0.01663 kg/m^3 and t_s = 19.4°C.

To solve for the rates of evaporation and heat transfer, first calculate the Reynolds number using air properties at t_f = (25 + 19.4)/2 = 22.2°C.

$$\text{Re}_L = \frac{\rho u_\infty L}{\mu} = \frac{(1.191)(10)(0.1)}{1.809 \times 10^{-5}} = 65\,837$$

where L = 0.1 m, the length of the plate in the direction of flow. Because Re_L < 500 000, flow is laminar over the entire length of the plate; therefore,

$$\text{Sh} = 0.664\,\text{Re}^{1/2}\text{Sc}^{1/3} = 144$$

$$h_M = \frac{\text{Sh}\,D_v}{L} = 0.0363 \text{ m/s}$$

$$\dot{m} = h_M A(\rho_s - \rho_\infty) = 2.679 \times 10^{-5} \text{ kg/s}$$

$$q = \dot{m}\, h_{fg} = 65.8 \text{ W}$$

The same value for q would be obtained by calculating the Nusselt number and heat transfer coefficient h and setting $q = hA(t_\infty - t_s)$.

The kind of similarity between heat and mass transfer that results in Equations (31) to (34) can also be shown to exist between heat and momentum transfer. Chilton and Colburn (1934) used this similarity to relate Nusselt number to friction factor by the analogy

$$j_H = \frac{\text{Nu}}{\text{Re Pr}^{(1-n)}} = \text{St Pr}^n = \frac{f}{2} \tag{35}$$

where n = 2/3, St = Nu/(Re Pr) is the Stanton number, and j_H is the Chilton-Colburn j-factor for heat transfer. Substituting Sh for Nu and Sc for Pr in Equations (33) and (34) gives the Chilton-Colburn j-factor for mass transfer, j_D:

$$j_D = \frac{\text{Sh}}{\text{Re Sc}^{(1-n)}} = \text{St}_m\text{Sc}^n = \frac{f}{2} \tag{36}$$

where $\text{St}_m = \text{Sh}P_{Am}/(\text{Re Sc})$ is the Stanton number for mass transfer. Equations (35) and (36) are called the **Chilton-Colburn *j*-factor analogy**.

The power of the Chilton-Colburn j-factor analogy is represented in Figures 8 to 11. Figure 8 plots various experimental values of j_D from a flat plate with flow parallel to the plate surface. The solid line, which represents the data to near perfection, is actually $f/2$ from Blasius' solution of laminar flow on a flat plate (left-hand portion of the solid line) and Goldstein's solution for a turbulent boundary layer (right-hand portion). The right-hand part also represents McAdams' (1954) correlation of turbulent flow heat transfer coefficient for a flat plate.

A **wetted-wall column** is a vertical tube in which a thin liquid film adheres to the tube surface and exchanges mass by evaporation or absorption with a gas flowing through the tube. Figure 9 illustrates typical data on vaporization in wetted-wall columns, plotted as j_D versus Re. The point spread with variation in $\mu/\rho D_v$ results from Gilliland's finding of an exponent of 0.56, not 2/3, representing the effect of the Schmidt number. Gilliland's equation can be written as follows:

$$j_D = 0.023\ \text{Re}^{-0.17}\left(\frac{\mu}{\rho D_v}\right)^{-0.56} \tag{37}$$

Licensed for single user. © 2021, ASHRAE, Inc.

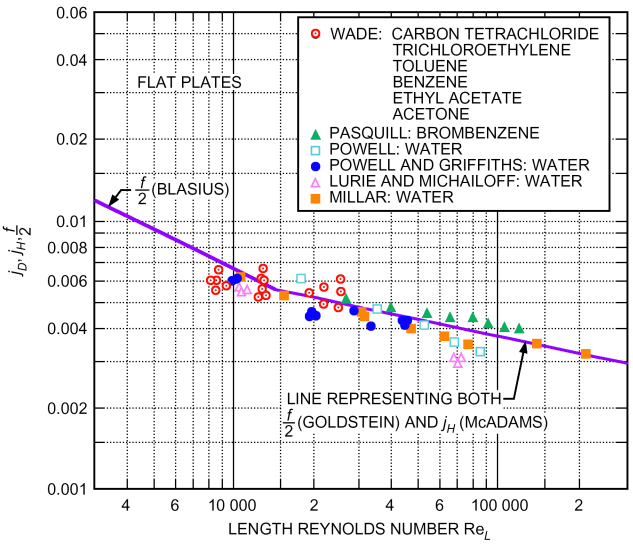

Fig. 8 Mass Transfer from Flat Plate

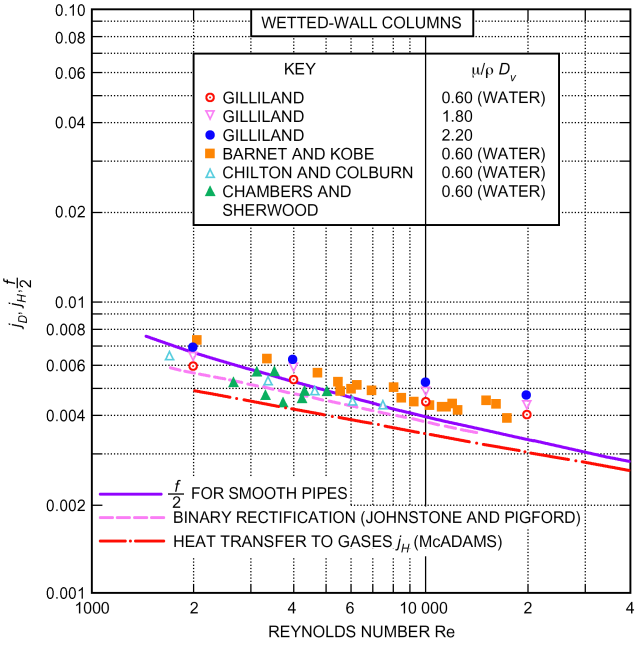

Fig. 9 Vaporization and Absorption in Wetted-Wall Column

Similarly, McAdams' (1954) equation for heat transfer in pipes can be expressed as

$$j_H = 0.023\ \mathrm{Re}^{-0.20}\left(\frac{c_p\mu}{k}\right)^{-0.7} \tag{38}$$

This is represented by the dash-dot curve in Figure 9, which falls below the mass transfer data. The curve $f/2$, representing friction in smooth tubes, is the upper, solid curve.

Data for liquid evaporation from single cylinders into gas streams flowing transversely to the cylinders' axes are shown in Figure 10. Although the dash-dot line in Figure 10 represents the data, it is actually taken from McAdams (1954) as representative of a large collection of data on heat transfer to single cylinders placed transverse to airstreams. To compare these data with friction, it is necessary to distinguish between total drag and skin friction.

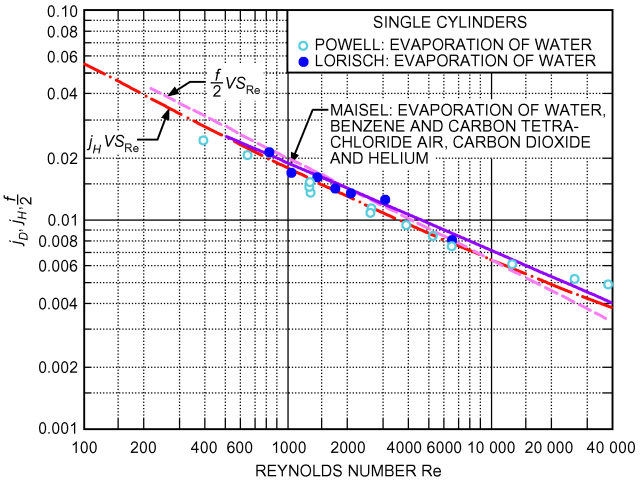

Fig. 10 Mass Transfer from Single Cylinders in Crossflow

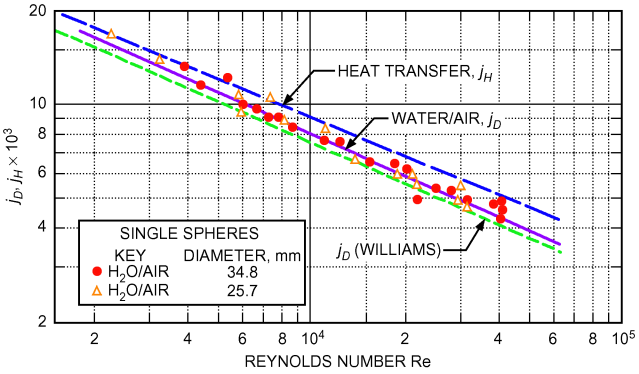

Fig. 11 Mass Transfer from Single Spheres

Because the analogies are based on skin friction, normal pressure drag must be subtracted from the measured total drag. At Re = 1000, skin friction is 12.6% of the total drag; at Re = 31 600, it is only 1.9%. Consequently, values of $f/2$ at a high Reynolds number, obtained by the difference, are subject to considerable error.

In Figure 11, data on evaporation of water into air for single spheres are presented. The solid line, which best represents these data, agrees with the dashed line representing McAdams' correlation for heat transfer to spheres. These results cannot be compared with friction or momentum transfer because total drag has not been allocated to skin friction and normal pressure drag. Application of these data to air/water-contacting devices such as air washers and spray cooling towers is well substantiated.

When the temperature of the heat exchanger surface in contact with moist air is below the air's dew-point temperature, vapor condensation occurs. Typically, air dry-bulb temperature and humidity ratio both decrease as air flows through the exchanger. Therefore, sensible and latent heat transfer occur simultaneously. This process is similar to one that occurs in a spray dehumidifier and can be analyzed using the same procedure; however, this is not generally done.

Cooling coil analysis and design are complicated by the problem of determining transport coefficients h, h_M, and f. It would be convenient if heat transfer and friction data for dry heating coils could be used with the Colburn analogy to obtain the mass transfer coefficients, but this approach is not always reliable, and Guillory and McQuiston (1973) and Helmer (1974) show that the analogy is not consistently true. Figure 12 shows j-factors for a simple parallel-

Licensed for single user. © 2021, ASHRAE, Inc.

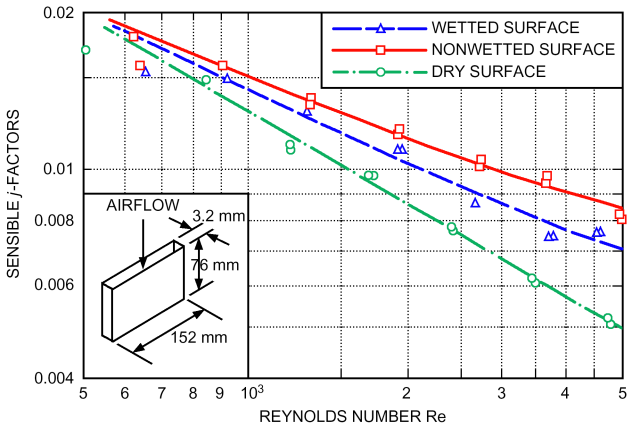

Fig. 12 Sensible Heat Transfer *j*-Factors for Parallel Plate Exchanger

plate exchanger for different surface conditions with sensible heat transfer. Mass transfer *j*-factors and friction factors exhibit the same behavior. Dry-surface *j*-factors fall below those obtained under dehumidifying conditions with the surface wet. At low Reynolds numbers, the boundary layer grows quickly; the droplets are soon covered and have little effect on the flow field. As the Reynolds number increases, the boundary layer becomes thin and more of the total flow field is exposed to the droplets. Roughness caused by the droplets induces mixing and larger *j*-factors.

The data in Figure 12 cannot be applied to all surfaces, because the length of the flow channel is also an important variable. However, water collecting on the surface is mainly responsible for breakdown of the *j*-factor analogy. The *j*-factor analogy is approximately true when surface conditions are identical. Under some conditions, it is possible to obtain a film of condensate on the surface instead of droplets. Guillory and McQuiston (1973) and Helmer (1974) related dry sensible *j*- and *f*-factors to those for wetted dehumidifying surfaces.

The equality of j_H, j_D, and $f/2$ for certain streamlined shapes at low mass transfer rates has experimental verification. For flow past bluff objects, j_H and j_D are much smaller than $f/2$, based on total pressure drag. The heat and mass transfer, however, still relate in a useful way by equating j_H and j_D.

Example 6. Using solid cylinders of volatile solids (e.g., naphthalene, camphor, dichlorobenzene) with airflow normal to these cylinders, Bedingfield and Drew (1950) found that the ratio between the heat and mass transfer coefficients could be closely correlated by the following relation:

$$\frac{h}{\rho h_M} = [1230\ \text{J/(kg·K)}]\left(\frac{\mu}{\rho D_v}\right)^{0.56}$$

For completely dry air at 21°C flowing at a velocity of 9.5 m/s over a wet-bulb thermometer of diameter d = 7.5 mm, determine the heat and mass transfer coefficients from Figure 10 and compare their ratio with the Bedingfield-Drew relation.

Solution: For dry air at 21°C and standard pressure, $\rho = 1.198$ kg/m^3, $\mu = 1.82 \times 10^{-5}$ kg/(s·m), $k = 0.02581$ W/(m·K), and $c_p = 1.006$ kJ/(kg·K). From Equation (10), $D_v = 25.13$ mm^2/s. Therefore,

$$\text{Re}_{da} = \rho u_\infty d/\mu = 1.198 \times 9.5 \times 7.5/(1000 \times 1.82 \times 10^{-5}) = 4690$$

$$\text{Pr} = c_p\mu/k = 1.006 \times 1.82 \times 10^{-5} \times 1000/0.02581 = 0.709$$

$$\text{Sc} = \mu/\rho D_v = 1.82 \times 10^{-5} \times 10^6/(1.198 \times 25.13) = 0.605$$

From Figure 10 at $\text{Re}_{da} = 4700$, read $j_H = 0.0089$, and $j_D = 0.010$. From Equations (35) and (36),

$$h = j_H \rho c_p u_\infty/(\text{Pr})^{2/3}$$
$$= 0.0089 \times 1.198 \times 1.006 \times 9.5 \times 1000/(0.709)^{2/3}$$
$$= 128\ \text{W/(m}^2\text{·K)}$$
$$h_M = j_D u_\infty/(\text{Sc})^{2/3} = 0.010 \times 9.5/(0.605)^{2/3}$$
$$= 0.133\ \text{m/s}$$
$$h/\rho h_M = 128/(1.198 \times 0.133) = 803\ \text{J/(kg·K)}$$

From the Bedingfield-Drew relation,

$$h/\rho h_M = 1230(0.605)^{0.56} = 928\ \text{J/(kg·K)}$$

Equations (36) and (37) are called the Reynolds analogy when Pr = Sc = 1. This suggests that $h/\rho h_M = c_p = 1006$ J/(kg·K). This close agreement is because the ratio Sc/Pr is 0.605/0.709 or 0.85, so that the exponent of these numbers has little effect on the ratio of the transfer coefficients.

The extensive developments for calculating heat transfer coefficients can be applied to calculate mass transfer coefficients under similar geometrical and flow conditions using the *j*-factor analogy. For example, Table 8 of Chapter 4 lists equations for calculating heat transfer coefficients for flow inside and normal to pipes. Each equation can be used for mass transfer coefficient calculations by equating j_H and j_D and imposing the same restriction to each stated in Table 8 of Chapter 4. Similarly, mass transfer experiments often replace corresponding heat transfer experiments with complex geometries where exact boundary conditions are difficult to model (Sparrow and Ohadi 1987a, 1987b).

The *j*-factor analogy is useful only at low mass transfer rates. As the rate increases, the movement of matter normal to the transfer surface increases the convective velocity. For example, if a gas is blown from many small holes in a flat plate placed parallel to an airstream, the boundary layer thickens, and resistance to both mass and heat transfer increases with increasing blowing rate. Heat transfer data are usually collected at zero or, at least, insignificant mass transfer rates. Therefore, if such data are to be valid for a mass transfer process, the mass transfer rate (i.e., the blowing) must be low.

The *j*-factor relationship $j_H = j_D$ can still be valid at high mass transfer rates, but neither j_H nor j_D can be represented by data at zero mass transfer conditions. Chapter 24 of Bird et al. (1960) and Eckert and Drake (1972) have detailed information on high mass transfer rates.

Lewis Relation

Heat and mass transfer coefficients are satisfactorily related at the same Reynolds number by equating the Chilton-Colburn *j*-factors. Comparing Equations (35) and (36) gives

$$\text{St}\,\text{Pr}^n = f/2 = \text{St}_m\text{Sc}^n$$

Inserting the definitions of St, Pr, St_m, and Sc gives

$$\frac{h}{\rho c_p \bar{u}}\left(\frac{c_p\mu}{k}\right)^{2/3} = \frac{h_M P_{Am}}{\bar{u}}\left(\frac{\mu}{\rho D_v}\right)^{2/3}$$

or

$$\frac{h}{h_M \rho c_p} = P_{Am}\left[\frac{(\mu/\rho D_v)}{(c_p\mu/k)}\right]^{2/3} = P_{Am}(\alpha/D_v)^{2/3} \quad (39)$$

The quantity α/D_v is the **Lewis number Le**. Its magnitude expresses relative rates of propagation of energy and mass within a system. It is fairly insensitive to temperature variation. For air and water vapor mixtures, the ratio is (0.60/0.71) or 0.845, and $(0.845)^{2/3}$ is 0.894. At low diffusion rates, where the heat/mass transfer analogy is

Licensed for single user. © 2021, ASHRAE, Inc.

valid, P_{Am} is essentially unity. Therefore, for air and water vapor mixtures,

$$h/h_M \rho c_p \approx 1 \tag{40}$$

The ratio of the heat transfer coefficient to the mass transfer coefficient equals the specific heat per unit volume of the mixture at constant pressure. This relation [Equation (40)] is usually called the Lewis relation and is nearly true for air and water vapor at low mass transfer rates. It is generally not true for other gas mixtures because the ratio Le of thermal to vapor diffusivity can differ from unity. Agreement between wet-bulb temperature and adiabatic saturation temperature is a direct result of the nearness of the Lewis number to unity for air and water vapor.

The Lewis relation is valid in turbulent flow whether or not α/D_v equals 1 because eddy diffusion in turbulent flow involves the same mixing action for heat exchange as for mass exchange, and this action overwhelms any molecular diffusion. Deviations from the Lewis relation are, therefore, caused by a laminar boundary layer or a laminar sublayer and buffer zone where molecular transport phenomena are the controlling factors.

3. SIMULTANEOUS HEAT AND MASS TRANSFER BETWEEN WATER-WETTED SURFACES AND AIR

A simplified method used to solve simultaneous heat and mass transfer problems was developed using the Lewis relation, and it gives satisfactory results for most air-conditioning processes. Extrapolation to very high mass transfer rates, where the simple heat-mass transfer analogy is not valid, leads to erroneous results.

Enthalpy Potential

The water vapor concentration in the air is the humidity ratio W, defined as

$$W \equiv \frac{\rho_B}{\rho_A} \tag{41}$$

A mass transfer coefficient is defined using W as the driving potential:

$$m''_B = K_M(W_i - W_\infty) \tag{42}$$

where the coefficient K_M is in kg/(s·m^2). For dilute mixtures, $\rho_{Ai} \cong \rho_{A\infty}$; that is, the partial mass density of dry air changes by only a small percentage between interface and free stream conditions. Therefore,

$$m''_B = \frac{K_M}{\rho_{Am}}(\rho_{Bi} - \rho_\infty) \tag{43}$$

where ρ_{Am} = mean density of dry air, kg/m^3. Comparing Equation (43) with Equation (26) shows that

$$h_M = \frac{K_M}{\rho_{Am}} \tag{44}$$

The **humid specific heat** c_{pm} of the airstream is, by definition (Mason and Monchick 1965),

$$c_{pm} = (1 + W_\infty)c_p \tag{45a}$$

or

$$c_{pm} = (\rho/\rho_{A\infty})c_p \tag{45b}$$

where c_{pm} is in kJ/(kg$_{da}$·K).

Substituting from Equations (44) and (45b) into Equation (40) gives

$$\frac{h\rho_{Am}}{K_M \rho_{A\infty} c_{pm}} = 1 \approx \frac{h}{K_M c_{pm}} \tag{46}$$

because $\rho_{Am} \cong \rho_{A\infty}$ because of the small change in dry-air density. Using a mass transfer coefficient with the humidity ratio as the driving force, the Lewis relation becomes ratio of heat to mass transfer coefficient equals humid specific heat.

For the plate humidifier illustrated in Figure 7, the total heat transfer from liquid to interface is

$$q'' = q''_A + m''_B h_{fg} \tag{47}$$

Using the definitions of the heat and mass transfer coefficients gives

$$q'' = h(t_i - t_\infty) + K_M(W_i - W_\infty)h_{fg} \tag{48}$$

Assuming Equation (46) is valid gives

$$q'' = K_M[c_{pm}(t_i - t_\infty) + (W_i - W_\infty)h_{fg}] \tag{49}$$

The enthalpy of the air is approximately

$$h = c_{pa}(t - t_o) + Wh_s \tag{50}$$

The enthalpy h_s of the water vapor can be expressed by the ideal gas law as

$$h_s = c_{ps}(t - t_o) + h_{fgo} \tag{51}$$

where the base of enthalpy is taken as saturated water at temperature t_o. Combining Equations (50) and (51) gives

$$h = (c_{pa} + Wc_{ps})t + Wh_{fgo} = c_{pm}t + Wh_{fgo} \tag{52}$$

(53)

If small changes in the latent heat of vaporization of water with temperature are neglected when comparing Equations (50) and (52), the total heat transfer can be written as

$$q'' = K_M(h_i - h_\infty) \tag{54}$$

Where the driving potential for heat transfer is temperature difference and the driving potential for mass transfer is mass concentration or partial pressure, the driving potential for simultaneous transfer of heat and mass in an air water/vapor mixture is, to a close approximation, enthalpy.

Basic Equations for Direct-Contact Equipment

Air-conditioning equipment can be classified by whether the air and water used as a cooling or heating fluid are (1) in direct contact or (2) separated by a solid wall. Examples of the former are air washers and cooling towers; an example of the latter is a direct-expansion refrigerant (or water) cooling and dehumidifying coil. In both cases, the airstream is in contact with a water surface. Direct contact implies contact directly with the cooling (or heating) fluid. In the dehumidifying coil, contact is direct with condensate removed from the airstream, but is indirect with refrigerant flowing inside the coil tubes. These two cases are treated separately because the surface areas of direct-contact equipment cannot be evaluated.

For the direct-contact spray chamber air washer of cross-sectional area A_{cs} and length l (Figure 13), the steady mass flow rate of dry air per unit cross-sectional area is

Licensed for single user. © 2021, ASHRAE, Inc.

$$m_a / A_{cs} = G_a \tag{55}$$

and the corresponding mass flux of water flowing parallel with the air is

$$m_L / A_{cs} = G_L \tag{56}$$

where

m_a = mass flow rate of air, kg/s
G_a = mass flux or flow rate per unit cross-sectional area for air, kg/(s·m²)
m_L = mass flow rate of liquid, kg/s
G_L = mass flux or flow rate per unit cross-sectional area for liquid, kg/(s·m²)

Because water is evaporating or condensing, G_L changes by an amount dG_L in a differential length dl of the chamber. Similar changes occur in temperature, humidity ratio, enthalpy, and other properties.

Because evaluating the true surface area in direct-contact equipment is difficult, it is common to work on a unit volume basis. If a_H and a_M are the areas of heat transfer and mass transfer surface per unit of chamber volume, respectively, the total surface areas for heat and mass transfer are

$$A_H = a_H A_{cs} l \quad \text{and} \quad A_M = a_M A_{cs} l \tag{57}$$

The basic equations for the process occurring in the differential length dl can be written for

Mass transfer

$$-dG_L = G_a\, dW = K_M a_M (W_i - W) dl \tag{58}$$

That is, the water evaporation rate, air moisture content increase, and mass transfer rate are all equal.

Heat transfer to air

$$G_a c_{pm} dt_a = h_a a_H (t_i - t_a) dl \tag{59}$$

Total energy transfer to air

$$G_a (c_{pm} dt_a + h_{fgo} dW) = [K_M a_M (W_i - W) h_{fg} + h_a a_H (t_i - t_a)] dl \tag{60}$$

Assuming $a_H = a_M$ and Le = 1, and neglecting small variations in h_{fg}, Equation (59) reduces to

$$G_a dh = K_M a_M (h_i - h) dl \tag{61}$$

The heat and mass transfer areas of spray chambers are assumed to be identical ($a_H = a_M$). Where packing materials, such as wood slats or Raschig rings, are used, the two areas may be considerably different because the packing may not be wet uniformly. The validity of the Lewis relation was discussed previously. It is not necessary to account for small changes in latent heat h_{fg} after making the two previous assumptions.

Energy balance

$$G_a dh = \pm G_L c_L dt_L \tag{62}$$

A minus sign refers to parallel flow of air and water; a plus refers to counterflow (water flow in the opposite direction from airflow).

The water flow rate changes between inlet and outlet as a result of the mass transfer. For exact energy balance, the term $(c_L t_L dG_L)$ should be added to the right side of Equation (61). The percentage change in G_L is quite small in usual applications of air-conditioning equipment and, therefore, can be ignored.

Heat transfer to water

$$\pm G_L c_L dt_L = h_L a_H (t_L - t_i) dl \tag{63}$$

Equations (57) to (62) are the basic relations for solution of simultaneous heat and mass transfer processes in direct-contact air-conditioning equipment.

To facilitate use of these relations in equipment design or performance, three other equations can be extracted from the above set. Combining Equations (60), (61), and (62) gives

$$\frac{h - h_i}{t_L - t_i} = -\frac{h_L a_H}{K_M a_M} = -\frac{h_L}{K_M} \tag{64}$$

Equation (63) relates the enthalpy potential for total heat transfer through the gas film to the temperature potential for this same transfer through the liquid film. Physical reasoning leads to the conclusion that this ratio is proportional to the ratio of gas film resistance ($1/K_M$) to liquid film resistance ($1/h_L$). Combining Equations (58), (60), and (46) gives

$$\frac{dh}{dt_a} = \frac{h - h_i}{t_a - t_i} \tag{65}$$

Similarly, combining Equations (57), (58), and (46) gives

$$\frac{dW}{dt_a} = \frac{W - W_i}{t_a - t_i} \tag{66}$$

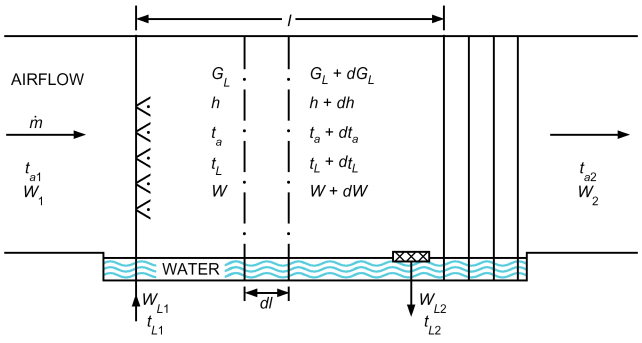

Fig. 13 Air Washer Spray Chamber

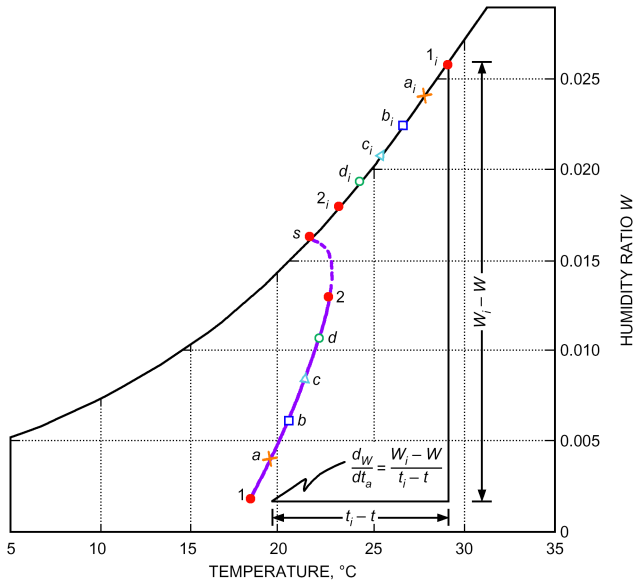

Fig. 14 Air Washer Humidification Process on Psychrometric Chart

Licensed for single user. © 2021, ASHRAE, Inc.

Equation (65) indicates that, at any cross section in the spray chamber, the instantaneous slope of the air path dW/dt_a on a psychrometric chart is determined by a straight line connecting the air state with the interface saturation state at that cross section. In Figure 14, state 1 represents the state of air entering the parallel-flow air washer chamber of Figure 13. The washer operates as a heating and humidifying apparatus, so the interface saturation state of the water at air inlet is the state designated 1_i. Therefore, the initial slope of the air path is along a line directed from state 1 to state 1_i. As the air is heated, the water cools and the interface temperature drops. Corresponding air states and interface saturation states are indicated by the letters *a*, *b*, *c*, and *d* in Figure 14. In each instance, the air path is directed toward the associated interface state. The interface states are derived from Equations (61) and (63). Equation (61) describes how air enthalpy changes with water temperature; Equation (63) describes how the interface saturation state changes to accommodate this change in air and water conditions. The solution for the interface state on the normal psychrometric chart of Figure 14 can be determined either by trial and error from Equations (61) and (63) or by a complex graphical procedure (Kusuda 1957).

Air Washers

Air washers are direct-contact apparatus used to (1) simultaneously change the temperature and humidity content of air passing through the chamber and (2) remove air contaminants such as dust and odors. Adiabatic spray washers, which have no external heating or chilling source, are used to cool and humidify air. Chilled-spray air washers have an external chiller to cool and dehumidify air. Heated-spray air washers, with an external heating source that provides additional energy for water evaporation, are used to humidify and possibly heat air.

Example 7. A parallel-flow air washer with the following design conditions is to be designed (see Figure 13).

Water temperature at inlet $t_{L1} = 35°C$
Water temperature at outlet $t_{L2} = 23.9°C$
Air temperature at inlet $t_{a1} = 18.3°C$
Air wet-bulb at inlet $t'_{a1} = 7.2°C$
Air mass flow rate per unit area $G_a = 1.628$ kg/(s·m²)
Spray ratio $G_L/G_a = 0.70$
Air heat transfer coefficient per cubic metre of chamber volume $h_a a_H = 1.34$ kW/(m³·K)
Liquid heat transfer coefficient per cubic metre of chamber volume $h_L a_H = 16.77$ kW/(m³·K)
Air volumetric flow rate $Q = 3.07$ m³/s

Solution: The air mass flow rate $m_a = 3.07 \times 1.20 = 3.68$ kg/s; the required spray chamber cross-sectional area is then $A_{cs} = m_a/G_a = 3.68/1.628 = 2.26$ m². The mass transfer coefficient is given by the Lewis relation [Equation (46)] as

$$K_M a_M = (h_a a_H)/c_{pm} = 1.34/1.005 = 1.33 \text{ kg/(m}^3\cdot\text{s)}$$

Figure 15 shows the enthalpy/temperature psychrometric chart with the graphical solution for the interface states and the air path through the washer spray chamber.

1. Enter bottom of chart with t'_{a1} of 7.2°C, and follow up to saturation curve to establish air enthalpy h_1 of 41.1 kJ/kg. Extend this enthalpy line to intersect initial air temperature t_{a1} of 18.3°C (state 1 of air) and initial water temperature t_{L1} of 35°C at point A. (Note that the temperature scale is used for both air and water temperatures.)
2. Through point A, construct the *energy balance* line A-B with a slope of

$$\frac{dh}{dt_L} = -\frac{c_L G_L}{G_a} = -2.95$$

Point B is determined by intersection with the leaving water temperature $t_{L2} = 23.9°C$. The negative slope here is a consequence of the parallel flow, which results in the air/water mixture's approaching, but not reaching, the common saturation state *s*. (Line A-B has no physical significance in representing any *air state* on the psychrometric chart. It is merely a construction line in the graphical solution.)

3. Through point A, construct the *tie-line* A-1_i having a slope of

$$\frac{h - h_i}{t_L - t_i} = -\frac{h_L a_H}{K_M a_M} = -\frac{16.77}{1.33} = -12.6$$

The intersection of this line with the saturation curve gives the initial interface state 1_i at the chamber inlet. [Note how the energy balance line and tie-line, representing Equations (61) and (63), combine for a simple graphical solution on Figure 15 for the interface state.]

4. The initial slope of the air path can now be constructed, according to Equation (64), drawing line 1-*a* toward the initial interface state 1_i. (Length of line 1-*a* depends on the degree of accuracy required in the solution and the rate at which the slope of the air path changes.)
5. Construct the horizontal line *a*-M, locating point M on the energy-balance line. Draw a new tie-line (slope of –12.6 as before) from M to a_i locating interface state a_i. Continue the air path from *a* to *b* by directing it toward the new interface state a_i. (Note that the change in slope of the air path from 1-*a* to *a*-*b* is quite small, justifying the path incremental lengths used.)
6. Continue in the manner of step 5 until point 2, the final state of air leaving the chamber, is reached. In this example, six steps are used in the graphical construction, with the following results:

State	1	*a*	*b*	*c*	*d*	2
t_L	35	32.8	30.6	28.3	26.1	23.9
h	41.1	47.7	54.3	60.8	67.4	73.9
t_i	29.2	27.9	26.7	25.4	24.2	22.9
h_i	114.4	108.0	102.3	96.9	91.3	86.4
t_a	18.3	19.3	20.3	21.1	21.9	22.4

The final state of air leaving the washer is $t_{a2} = 22.4°C$ and $h_2 = 73.6$ kJ/kg (wet-bulb temperature $t'_{a2} = 19.4°C$).

7. The final step involves calculating the required length of the spray chamber. From Equation (61),

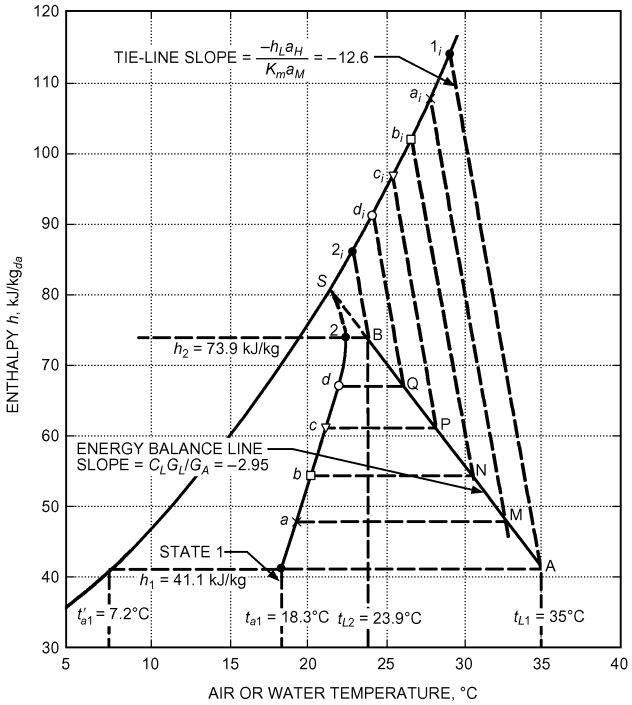

Fig. 15 Graphical Solution for Air-State Path in Parallel-Flow Air Washer

Licensed for single user. © 2021, ASHRAE, Inc.

$$l = \frac{G_a}{K_M a_M} \int_1^2 \frac{dh}{(h_i - h)}$$

The integral is evaluated graphically by plotting $1/(h_i - h)$ versus h, as shown in Figure 16. Any satisfactory graphical method can be used to evaluate the area under the curve. Simpson's rule with four equal increments of Δh equal to 8.2 gives

$$N = \int_1^2 \frac{dh}{(h_i - h)} \approx (\Delta h/3)(y_1 + 4y_2 + 2y_3 + 4y_4 + y_5)$$

$$N = (8.2/3)[0.0136 + (4 \times 0.0167) + (2 \times 0.0238) + (4 \times 0.0372) + 0.0800] = 0.975$$

Therefore, the design length is $l = (1.628/1.33)(0.975) = 1.19$ m.

This method can also be used to predict performance of existing direct-contact equipment and to determine transfer coefficients when performance data from test runs are available. By knowing the water and air temperatures entering and leaving the chamber and the spray ratio, it is possible to determine by trial and error the proper slope of the tie-line necessary to achieve the measured final air state. The tie-line slope gives the ratio $h_L a_H / K_M a_M$; $K_M a_M$ is found from the integral relationship in Example 7 from the known chamber length l.

Additional descriptions of air spray washers and general performance criteria are given in Chapter 41 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

Cooling Towers

A cooling tower is a direct-contact heat exchanger in which waste heat picked up by the cooling water from a refrigerator, air conditioner, or industrial process is transferred to atmospheric air by cooling the water. Cooling is achieved by breaking up the water flow to provide a large water surface for air, moving by natural or forced convection through the tower, to contact the water. Cooling towers may be counterflow, crossflow, or a combination of both.

The temperature of water leaving the tower and the packing depth needed to achieve the desired leaving water temperature are of primary interest for design. Therefore, the mass and energy balance equations are based on an overall coefficient K, which is based on (1) the enthalpy driving force from h at the bulk water temperature and (2) neglecting the film resistance. Combining Equations (60) and (61) and using the parameters described previously yields

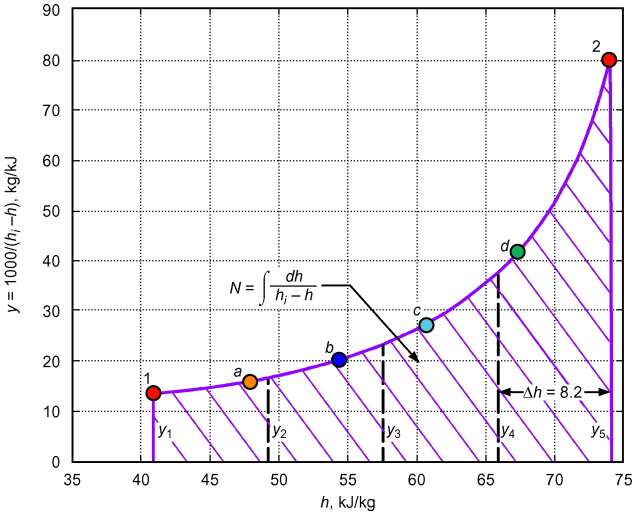

Fig. 16 Graphical Solution of $\int dh/(h_i - h)$

$$G_L c_L dt = K_M a_M (h_i - h) dl = G_a dh = \frac{K_a dV (h' - h_a)}{A_{cs}} \quad (67)$$

or

$$\frac{K_a V}{m_L} = \int_{t_1}^{t_2} \frac{c_L dt}{(h' - h_a)} \quad (68)$$

Chapter 40 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* covers cooling tower design in detail.

Cooling and Dehumidifying Coils

When water vapor is condensed out of an airstream onto an extended-surface (finned) cooling coil, the simultaneous heat and mass transfer problem can be solved by the same procedure set forth for direct-contact equipment. The basic equations are the same, except that the true surface area of coil A is known and the problem does not have to be solved on a unit-volume basis. Therefore, if, in Equations (57), (58), and (60), $a_M dl$ or $a_H dl$ is replaced by dA/A_{cs}, these equations become the basic heat, mass, and total energy transfer equations for indirect-contact equipment such as dehumidifying coils. The energy balance shown by Equation (61) remains unchanged. The heat transfer from the interface to the refrigerant now encounters the combined resistances of the condensate film ($R_L = 1/h_L$); the metal wall and fins, if any (R_m); and the refrigerant film ($R_r = A/h_r A_r$). If this combined resistance is designated as $R_i = R_L + R_m + R_r = 1/U_i$, Equation (62) becomes, for a coil dehumidifier,

$$\pm m_L c_L dt_L = U_i (t_L - t_i) dA \quad (69)$$

(plus sign for counterflow, minus sign for parallel flow).

The tie-line slope is then

$$\frac{h - h_i}{t_L - t_i} = \pm \frac{U_i}{K_M} \quad (70)$$

Figure 17 illustrates the graphical solution on a psychrometric chart for the air path through a dehumidifying coil with a constant refrigerant temperature. Because the tie-line slope is infinite in this case, the energy balance line is vertical. The corresponding interface and air states are denoted by the same letter symbols, and the solution follows the same procedure as in Example 7.

If the problem is to determine the required coil surface area for a given performance, the area is computed by the following relation:

$$A = \frac{\dot{m}_a}{K_M} \int_1^2 \frac{dh}{(h_i - h)} \quad (71)$$

This graphical solution on the psychrometric chart automatically determines whether any part of the coil is dry. Thus, in the example illustrated in Figure 17, entering air at state 1 initially encounters an interface saturation state 1_i, clearly below its dew-point temperature t_{d1}, so the coil immediately becomes wet. Had the graphical technique resulted in an initial interface state above the dew-point temperature of the entering air, the coil would be initially dry. The air would then follow a constant humidity ratio line (the sloping W = constant lines on the chart) until the interface state reached the air dew-point temperature.

Mizushina et al. (1959) developed this method not only for water vapor and air, but also for other vapor/gas mixtures. Chapter 23 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* shows another related method, based on AHRI *Standard* 410, of determining air-cooling and dehumidifying coil performance.

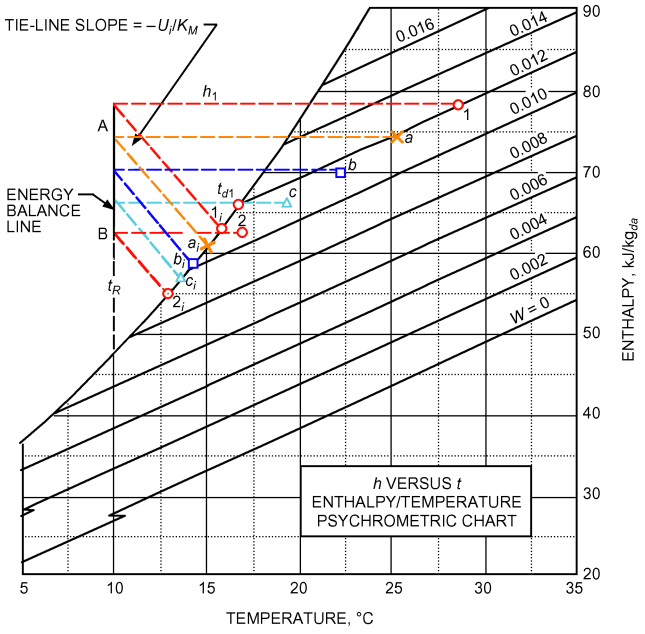

Fig. 17 Graphical Solution for Air-State Path in Dehumidifying Coil with Constant Refrigerant Temperature

Example 8. Air enters an air conditioner at 101.325 kPa, 30°C, and 85% rh at a rate of 0.2 m^3/s and leaves as saturated air at 14°C. Condensed moisture is also removed at 14°C. Calculate the heat transfer and moisture removal rate from the air.

Solution: Water mass flow is

$$m_w = m_a(W_1 - W_2)$$

and energy or heat transfer rate is

$$q_{out} = m_a(h_1 - h_2) - m_w h_w$$

Properties of air both at inlet and exit states can be determined from the psychrometric chart as follows:

$$h_1 = 89.0 \text{ kJ/kg}_{da}, \quad W_1 = 0.023 \text{ kg}_{H_2O}/\text{kg}_{da}$$
$$\text{specific volume} = 0.89 \text{ m}^3/\text{kg}_{da}$$
$$h_2 = 39.3 \text{ kJ/kg}_{da}, \quad W_2 = 0.010 \text{ kg}_{H_2O}/\text{kg}_{da}$$

Enthalpy of the condensate from saturated-water temperature table is

$$h_w = h_f \text{ at } 14°C = 58.81 \text{ kJ/kg}$$

Then,

$$m_a = 0.2/0.89 = 0.225 \text{ kg/s}$$

$$m_w = (0.225)(0.023 - 0.010) = 0.002925 \text{ kg/s}$$

$$q_{out} = (0.225)(89.0 - 29.3) - (0.002925)(58.81) = 11.0 \text{ kJ/s}$$

So, the air conditioner's heat transfer and moisture removal rates are 10.5 kJ/s and 0.002925 kg/s, respectively.

4. SYMBOLS

A = surface area, m^2
a = constant that depends on units used; or surface area per unit volume, m^2/m^3
A_{cs} = cross-sectional area, m^2
b = exponent or constant, dimensionless
C = molal concentration of solute in solvent, mol/m^3
c_L = specific heat of liquid, kJ/(kg·K)
c_p = specific heat at constant pressure, kJ/(kg·K)
c_{pm} = specific heat of moist air at constant pressure, kJ/(kg$_{da}$·K)
d = diameter, m
D_v = diffusion coefficient (mass diffusivity), mm^2/s
f = Fanning friction factor, dimensionless
G = mass flux, flow rate per unit of cross-sectional area, kg/(s·m^2)
h = enthalpy, kJ/kg; or heat transfer coefficient, W/(m^2·K)
h_{fg} = enthalpy of vaporization, kJ/kg
h_M = mass transfer coefficient, m/s
J = diffusive mass flux, kg/(s·m^2)
J^* = diffusive molar flux, mol/(s·m^2)
j_D = Colburn mass transfer group = Sh/(ReSc$^{1/3}$), dimensionless
j_H = Colburn heat transfer group = Nu/(RePr$^{1/3}$), dimensionless
k = thermal conductivity, W/(m·K)
K_M = mass transfer coefficient, kg/(s·m^2)
L = characteristic length, m
l = length, m
Le = Lewis number = α/D_v, dimensionless
M = relative molecular mass, kg/kg mol
m = rate of mass transfer, kg/s
m'' = mass flux, kg/(s·m^2)
m''^* = molar flux, mol/(s·m^2)
Nu = Nusselt number = hL/k, dimensionless
p = pressure, kPa
P_{Am} = logarithmic mean density factor
Pr = Prandtl number = $c_p\mu/k$, dimensionless
Q = volumetric flow rate, m^3/s
q = rate of heat transfer, W
q'' = heat flux per unit area, W/m^2
Re = Reynolds number = $\rho u L/\mu$, dimensionless
R_i = combined thermal resistance, (m^2·K)/W
R_L = thermal resistance of condensate film, (m^2·K)/W
R_m = thermal resistance across metal wall and fins, (m^2·K)/W
R_r = thermal resistance of refrigerant film, (m^2·K)/W
R_u = universal gas constant = 8.314 kJ/(mol·K)
Sc = Schmidt number = $\mu/\rho D_v$, dimensionless
Sh = Sherwood number = $h_M L/D_v$, dimensionless
St = Stanton number = $h/\rho c_p \bar{u}$, dimensionless
St$_m$ = mass transfer Stanton number = $h_M P_{Am}/\bar{u}$, dimensionless
T = absolute temperature, K
t = temperature, °C
u = velocity in x direction, m/s
U_i = overall conductance from refrigerant to air/water interface for dehumidifying coil, W/(m^2·K)
V = fluid stream velocity, m/s
v = velocity in y direction, m/s
v_i = velocity normal to mass transfer surface for component i, m/s
W = humidity ratio, kg$_w$/kg$_{da}$
X,Y,Z = coordinate direction, dimensionless
x,y,z = coordinate direction, m

Greek

α = thermal diffusivity = $k/\rho c_p$, m^2/s
ε = Lennard-Jones energy parameter
ε_D = eddy mass diffusivity, m^2/s
θ = time parameter, dimensionless
μ = absolute (dynamic) viscosity, kg/(m·s)
$\bar{\mu}$ = permeability, mg/(s·m·Pa)
ν = kinematic viscosity, m^2/s
ρ = mass density or concentration, kg/m^3
σ = characteristic molecular diameter, nm
τ = time
τ_i = shear stress in the x-y coordinate plane, N/m^2
ω = mass fraction, kg/kg
$\Omega_{D,AB}$ = temperature function in Equation (9)

Subscripts

A = gas component of binary mixture
a = air property
Am = logarithmic mean
B = more dilute gas component of binary mixture
c = critical state
da = dry-air property or air-side transfer quantity
H = heat transfer quantity
i = air/water interface value
L = liquid
M = mass transfer quantity
m = mean value or metal
min = minimum

Licensed for single user. © 2021, ASHRAE, Inc.

o = property evaluated at 0°C
s = water vapor property or transport quantity
w = water vapor
∞ = property of main fluid stream

Superscripts

$*$ = on molar basis
$-$ = average value
$'$ = wet bulb

AUTOMATIC control systems are designed to maintain temperature, humidity, pressure, energy use, power, lighting levels, and safe levels of indoor contaminants. Automatic control primarily modulates actuators; stages modes of action; or sequences the mechanical and electrical equipment on and off to satisfy load requirements, provide safe equipment operation, and maintain safe building contaminant levels. Automatic control systems can use digital, pneumatic, mechanical, electrical, and electronic control devices. Human intervention often involves scheduling equipment operation and adjusting control set points, but also includes tracking trends and programming control logic algorithms to fulfill building needs.

This chapter focuses on the fundamental concepts and devices normally used by a control system designer. It covers (1) control fundamentals, including terminology; (2) types of control components; (3) methods of connecting components to form various individual control loops, subsystems, or networks; and (4) commissioning and operation. Chapter 48 of the 2019 *ASHRAE Handbook—HVAC Applications* discusses the design of controls for specific HVAC applications.

1. GENERAL

1.1 TERMINOLOGY

An **open-loop** control does not have a direct feedback link between the value of the controlled variable and the controller. Open-loop control anticipates the effect of an external variable on the system and adjusts its output to minimize the expected deviation of the controlled variable from its set point. An example is an outdoor thermostat arranged to control heat to a building in proportion to the calculated load caused by changes in outdoor temperature. In essence, the designer presumes a fixed relationship between outdoor air temperature. The actual space temperature has no effect on this controller. Because there is no feedback on the controlled variable (space temperature), the control is an open loop.

A **closed-loop** or **feedback** control measures actual changes in the controlled variable and actuates the controlled device to bring about a change. The corrective action may continue until the controlled variable is at set point or within a prescribed tolerance. This arrangement of having the controller respond to the value of the controlled variable is known as feedback.

Every closed loop must contain a sensor, a controller, and a controlled device that will affect the sensor reading(s). Figure 1 shows the components of the typical control loop. The **sensor** measures the controlled variable and transmits to the controller a signal (pneumatic, electric, or electronic) having a pressure, voltage, or current value related by a known function to the value of the variable being measured. The **controller** compares this value with the set point and signals to the controlled device for corrective action. A controller can be hardware or software. A hardware controller is an analog device (e.g., thermostat, humidistat, pressure control) that continuously receives and acts on data. A software controller is a digital device (e.g., digital algorithm) that receives and acts on data on a sample-rate basis.

The **controlled variable** is the temperature, humidity, pressure, or other condition being controlled.

The **set point** is the desired value of the controlled variable. The controller seeks to maintain this set point. The controlled device reacts to signals from the controller to vary the control agent.

The **controlled device** is typically a valve, damper, heating element, or variable-speed drive.

The **control agent** is the medium manipulated by the controlled device. It may be air or gas flowing through a damper; gas, steam, or water flowing through a valve; or an electric current.

The **process** is the HVAC apparatus being controlled, such as a coil, fan, or humidifier. It reacts to the control agent's output and effects the change in the controlled variable.

Both open and closed control loops can be represented in the form of a **block diagram**, in which each component is modeled and represented in its own block. Figure 2 is a block diagram of the closed loop shown in Figure 1. Information flow from one component to the next is shown by lines between the blocks. The figure shows the set point being compared to the controlled variable. The difference is the **error**. If the error persists, it may be called offset,

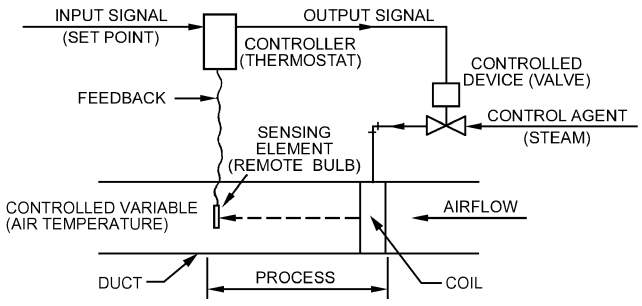

Fig. 1 Example of Feedback Control: Discharge Air Temperature Control

The preparation of this chapter is assigned to TC 1.4, Control Theory and Application.

drift, deviation, droop, or steady-state error. The error is fed into the controller, which sends an output signal to the controlled device (in this case, a valve that can change the amount of steam flow through the coil of Figure 1). The amount of steam flow is the input to the next block, which represents the process. From the process block comes the controlled variable, which is temperature. The controlled variable is sensed by the sensing element and fed to the controller as feedback, completing the loop.

Control loop performance is greatly affected by time lags, which are delay periods associated with seeing a control agent change reflected in the desired end-point condition. Time lags can cause control and modeling problems and should be understood and evaluated carefully. There are two types of time lags: first-order lags and dead time.

First-order lags involve the time it takes for the change to be absorbed by the system. If heat is supplied to a cold room, the room heats up gradually, even though heat may be applied at the maximum rate. The **time constant** is the unit of measure used to describe first-order lags and is defined as the time it takes for the controlled variable of a first-order, linear system to reach 63.2% of its final value when a step change in the input occurs. Components with small time constants alter their output rapidly to reflect changes in the input; components with a larger time constant are sluggish in responding to input changes.

Dead time (or time lag) is the time from when a change in the controller output is made to when the controlled variable exhibits a measurable response. Dead time can occur in the control loop of Figure 1 because of the transportation time of the air from the coil to the space. After a coil temperature changes, there is dead time while the supply air travels the distribution system and finally reaches the sensor in the space. The mass of air in the space further delays the coil temperature change's effect on the controlled variable (space temperature). Dead time can also be caused by a slow sensor or a time lag in the signal from the controller when it first begins to affect the output of the process. Dead time is most often associated with the time it takes to transport the media changed by the control agent from one place to another. Dead time may also be inadvertently added to a control loop by a digital controller with an excessive scan time. If the dead time is small, it may be ignored in the control system model; if it is significant, it must be considered.

Licensed for single user. © 2021 ASHRAE, Inc.

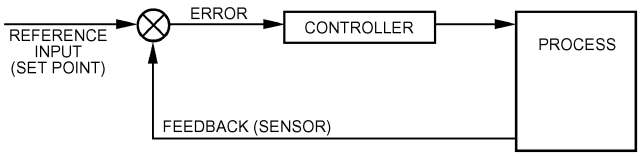

Fig. 2 Block Diagram of Discharge Air Temperature Control

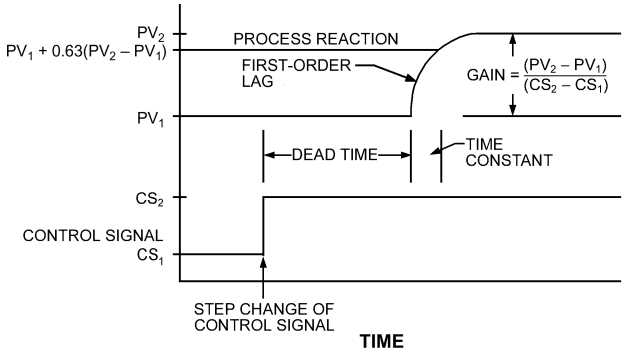

Fig. 3 Process Subjected to Step Input

Figure 1 depicts the mechanisms that create both first-order and dead-time lags, and Figure 3 shows the effect related to time. Dead time is the time it takes warmer air resulting from a higher set point to reach the space, followed by the first-order lag created by the wall on which the thermostat is mounted, and that of the temperature sensor (all of which warm gradually rather than all at once). The control loop must be tuned to account for the combined effect of each time lag. Note that, in most HVAC systems, the first-order lag element predominates.

The **gain** of a transfer function is the amount the output of the component changes per unit of change of input under steady-state conditions. If the element (valve, damper, and/or temperature/pressure differential) is linear, its gain remains constant. However, many control components are nonlinear and have gains that depend on the operating conditions. Figure 3 shows the response of the first-order-plus-dead-time process to a step change of the input signal. Note that the process shows no reaction during dead time, followed by a response that resembles a first-order exponential.

1.2 TYPES OF CONTROL ACTION

Control loops can be classified by the adjustability of the controlled device. A **two-position** controlled device has two operating states (e.g., open and closed), whereas a **modulating** controlled device has a continuous range of operating states (e.g., 0 to 100% open).

Two-Position Action

The control device shown in Figure 4 can be positioned only to a maximum or minimum state (i.e., on or off). Because two-position control is simple and inexpensive, it is used extensively for both industrial and commercial control. A typical home thermostat that starts and stops a furnace is an example.

Controller differential, as it applies to two-position control action, is the difference between a setting at which the controller operates to one position and a setting at which it operates to the other. Thermostat ratings usually refer to the differential (in degrees) that becomes apparent by raising and lowering the dial setting. This differential is known as the **manual differential** of the thermostat. When the same thermostat is applied to an operating system, the total change in temperature that occurs between a "turn-on" state and a "turn-off" state is usually different from the mechanical differential. The **operating differential** may be greater because of thermostat lag or hysteresis, or less because of heating or cooling anticipators built into the thermostat.

Anticipation Applied to Two-Position Action. This common variation of strictly two-position action is often used on room thermostats to reduce the operating differential. In heating thermostats, a heater element in the thermostat is energized during *on* periods, thus shortening the *on* time because the heater warms the thermostat (**heat anticipation**). The same anticipation action can be obtained in cooling thermostats by energizing a heater thermostat at *off* periods. In both cases, the percentage of *on* time is varied in proportion to the load, and the total cycle time remains relatively constant.

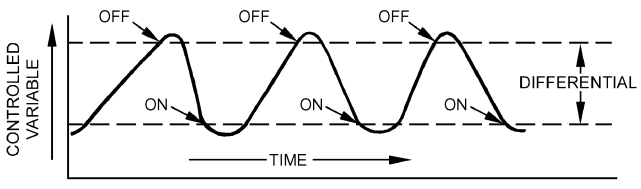

Fig. 4 Two-Position Control

Modulating Control

With modulating control, the controller's output can vary over its entire range. The following terms are used to describe this type of control:

- **Throttling range** is the amount of change in the controlled variable required to cause the controller to move the controlled device from one extreme to the other. It can be adjusted to meet job requirements. The throttling range is inversely proportional to proportional gain
- **Control point** is the actual value of the controlled variable at which the instrument is controlling. It varies within the controller's throttling range and changes with changing load on the system and other variables.
- **Offset**, or error signal, is the difference between the set point and actual control point under stable conditions. This is sometimes called drift, deviation, droop, or steady-state error.

In each of the following examples of modulating control, there is a set of parameters that quantifies the controller's response. The values of these parameters affect the control loop's speed, stability, and accuracy. In every case, control loop performance depends on matching (or **tuning**) the parameter values to the characteristics of the system under control.

Proportional Control. In proportional control, the controlled device is positioned proportionally in response to changes in the controlled variable (Figure 5). A proportional controller can be described mathematically by

$$V_p = K_p e + V_o \tag{1}$$

where

V_p = controller output
K_p = proportional gain parameter (inversely proportional to throttling range)
e = error signal or offset
V_o = offset adjustment parameter

The controller output is proportional to the difference between the sensed value, the controlled variable, and its set point. The controlled device is normally adjusted to be in the middle of its control range at set point by using an offset adjustment. This control is similar to that shown in Figure 5.

Proportional plus Integral (PI) Control. PI control improves on simple proportional control by adding another component to the control action that eliminates the offset typical of proportional control (Figure 6). Reset action may be described by

$$V_p = K_p e + K_i \int e \, d\theta + V_o \tag{2}$$

where

K_i = integral gain parameter
θ = time

The second term in Equation (2) implies that the longer error e exists, the more the controller output changes in attempting to eliminate the error. Proper selection of proportional and integral gain constants increases stability and eliminates offset, giving greater control accuracy.

Proportional-Integral-Derivative (PID) Control. This is PI control with a derivative term added to the controller. It varies with the value of the derivative of the error. The equation for PID control is

$$V_p = K_p e + K_i \int e \, d\theta + K_d \frac{de}{d\theta} + V_o \tag{3}$$

where

K_d = derivative gain parameter of controller
$de/d\theta$ = time derivative of error

Adding the derivative term gives some anticipatory action to the controller, which results in a faster response and greater stability. However, the derivative term also makes the controller more sensitive to noisy signals and harder to tune than a PI controller. Most HVAC control loops perform satisfactorily with PI control alone.

Adaptive Control. An adaptive controller adjusts the parameters that define its response as the dynamic characteristics of the process change. If the controller is PID based, then it adjusts feedback gains. An adaptive controller may be based on other feedback rules. The key is that it adjusts its parameters to match the characteristics of the process. When the process changes, the tuning parameters change to match it. Adaptive control is applied in HVAC systems because normal variations in operating conditions affect the characteristics relevant to tuning. For instance, the extent to which zone dampers are open or closed in a VAV system affects the way duct pressure responds to fan speed, and entering fluid temperatures at a coil affect the way the leaving temperature responds to the valve position. **Neural networks** and **self-learning performance-predictive** controllers are sophisticated adaptive controllers.

Fuzzy Logic. This type of control offers an alternative to traditional control algorithms. A fuzzy logic controller uses a series of "if-then" rules that emulates the way a human operator might control the process. Examples of fuzzy logic might include

- IF room temperature is high AND temperature is decreasing, THEN increase cooling a little.
- IF room temperature is high AND temperature is increasing, THEN increase cooling a lot.

The designer of a fuzzy logic controller must first define the rules and then define terms such as *high*, *increasing*, *decreasing*, *a lot*, and *a little*. Room temperature, for instance, might be mapped into a series of functions that include *very low*, *low*, *OK*, *high*, and *very high*. The "fuzzy" element is introduced when the functions overlap and the room temperature is, for example, 70% high and 30% OK. In this case, multiple rules are combined to determine the appropriate control action.

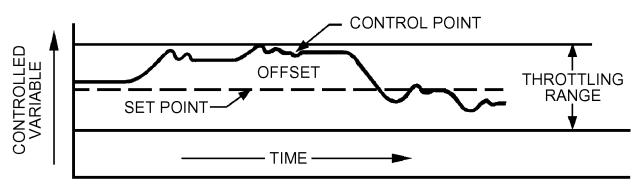

Fig. 5 Proportional Control Showing Variations in Controlled Variable as Load Changes

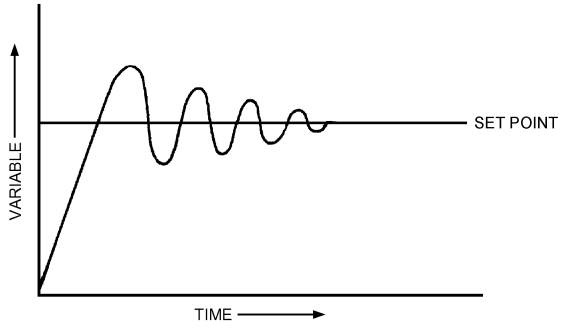

Fig. 6 Proportional plus Integral (PI) Control

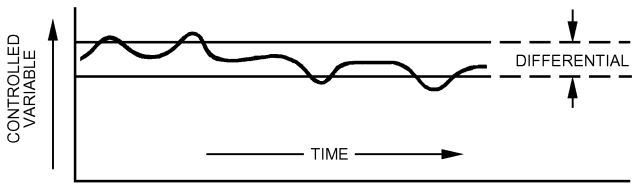

Fig. 7 Floating Control Showing Variations in Controlled Variable as Load Changes

Combinations of Two-Position and Modulating

Some control loops include two-position components in a system that exhibits nearly modulating response.

Timed Two-Position Control. This cycles a two-position heating or cooling element on and off quickly enough that the effect on the controlled temperature approximates a modulating device. In this case, a controller may adjust the duty cycle ("on-time" as a percentage of "cycle-time") as a modulating controlled variable. For example, an element may be turned on for two minutes and off for one minute when the deviation from set point is 2 K. Timed two-position action combines a modulating controller with a two-position controlled device.

Floating Control. This combines a modulating controlled device with a pair of two-position outputs. The controlled device has a continuous operating range, but the actuators that move it only turn on and off. The controller selects one of three operations: moving the controlled device toward its open position, moving it toward its closed position, or leaving the device in its current position. Control is accomplished by applying a pair of two-position contacts with a selected gap between their set points (Figure 7). Generally, a neutral zone between the two positions allows the controlled device to stop at any position when the controlled variable is within the differential of the controller. When the controlled variable falls outside the differential of the controller, the controller moves the controlled device in the proper direction. To function properly, the sensing element must react faster than the actuator drive time. If not, the control functions the same as a two-position control. When applied with a digital controller, floating-point control is also referred to as **tri-state control**.

Incremental Control. This variation of floating control varies the pulse action to open or close an actuator, depending on how close the controlled variable is to the set point. As the controlled variable comes close to the set point, the pulses become shorter. This allows closer control using floating motor actuators. When applied with a digital controller, incremental control is also referred to as **pulse-width-modulation (PWM) control**.

1.3 CLASSIFICATION OF CONTROL COMPONENTS BY ENERGY SOURCE

Control components may be classified according to the primary source of energy as follows:

- **Electric components** use electrical energy, either low or line voltage, as the energy source. The controller regulates electrical energy supplied to the controlled device. Control devices in this category include relays and electromechanical, electromagnetic, and solid-state regulating devices.

  Electronic components include signal conditioning, modulation, and amplification in their operation. Electronic systems use analog circuitry, rather than digital logic, to implement their control functions.

  A **digital electronic controller** receives analog electronic signals from sensors, converts the electronic signals to digital values, and performs mathematical operations on these values inside a microprocessor. Output from the digital controller takes the form of a digital value, which is then converted to an electronic signal to operate the actuator. The digital controller must sample its data because the microprocessor requires time for operations other than reading data. If the sampling interval for the digital controller is properly chosen to avoid second- and third-order harmonics, there will be no significant degradation in control performance from sampling.
- **Self-powered components** apply the power of the measured system to induce the necessary corrective action. The measuring system derives its energy from the process under control, without any auxiliary source of energy. Temperature changes at the sensor result in pressure or volume changes of the enclosed media that are transmitted directly to the operating device of the valve or damper. A component using a thermopile in a pilot flame to generate electrical energy is also self powered.
- **Pneumatic components** use compressed air, usually at a pressure of 100 to 140 kPa (gage), as an energy source. The air is generally supplied to the controller, which regulates the pressure supplied to the controlled device.

This method of classification can be extended to individual control loops and to complete control systems. For example, the room temperature control for a particular room that includes a pneumatic room thermostat and a pneumatically actuated reheat coil would be referred to as a pneumatic control loop. Many control systems use a combination of control components and are called **hybrid** systems.

Computers for Automatic Control

Computers perform the control functions in direct digital control (DDC) systems. Uses range from personal computers used as operator interfaces for DDC systems to embedded program microprocessors used to control variable-air-volume boxes, fan-coil units, heat pumps, and other terminal HVAC equipment. Other uses include primary HVAC equipment programmable controllers, distributed network controllers, and servers used to store DDC system trend data. Chapter 41 of the 2019 *ASHRAE Handbook—HVAC Applications* covers computer components and HVAC computer applications more extensively.

2. CONTROL COMPONENTS

2.1 CONTROL DEVICES

A control device is the component of a control loop used to vary the input (controlled variable). Both **valves** and **dampers** perform essentially the same function and must be properly sized and selected for the particular application. The control link to the valve or damper is called an **actuator** or **operator**, and uses electricity, compressed air, hydraulic fluid, or some other means to power the motion of the valve stem or damper linkage through its operating range. For additional information, see Chapter 37.

Valves

An automatic valve is designed to control the flow of steam, water, gas, or other fluids. It can be considered a variable orifice positioned by an actuator in response to impulses or signals from the controller. It may be equipped with a throttling plug, V-port, or rotating ball specially designed to provide a desired flow characteristic.

Types of automatic valves include the following:

A **three-way mixing valve** (Figure 8A) has two inlet connections and one outlet connection and a double-faced disk operating between two seats. It is used to mix two fluids entering through the two inlet connections and leaving through the common outlet, according to the position of the valve stem and disk.

A **three-way diverting valve** (Figure 8B) has one inlet connection and two outlet connections, and two separate disks and seats. It is used to divert flow to either of the outlets or to proportion the flow

Licensed for single user. © 2021 ASHRAE, Inc.

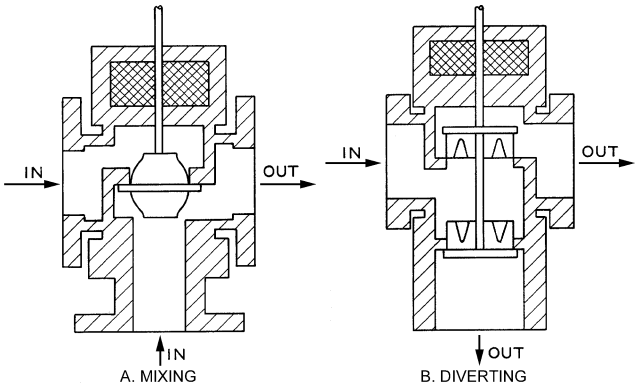

Fig. 8 Typical Three-Way Mixing and Diverting Globe Valves

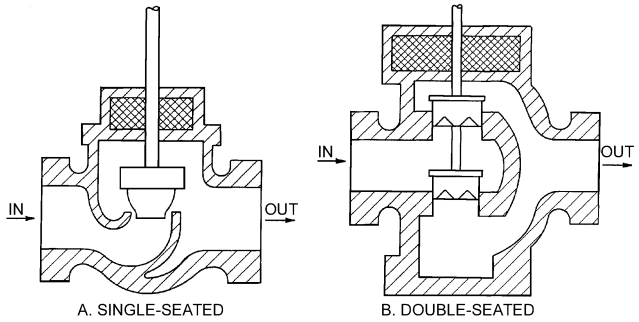

Fig. 9 Typical Single- and Double-Seated Two-Way Globe Valves

to both outlets. Three-way diverting valves are more expensive and have more complex applications, and generally are not used in typical HVAC systems.

A **two-way globe valve** may be either single or double seated. A **single-seated valve** (Figure 9A) is designed for tight shutoff. Appropriate disk materials for various pressures and media are used. A **double-seated** or **balanced valve** (Figure 9B) is designed so that the media pressure acting against the valve disk is essentially balanced, reducing the actuator force required. It is widely used where fluid pressure is too high to allow a single-seated valve to close or to modulate properly. It is not usually used where tight shutoff is required.

A **butterfly valve** consists of a heavy ring enclosing a disk that rotates on an axis at or near its center and is similar to a round single-blade damper. In principle, the disk seats against a ring machined within the body or a resilient liner in the body. Two butterfly valves can be used together to act like a three-way valve for mixing or diverting. In this arrangement, one valve is set up as normally open and the other is normally closed. In applications with pipe sizes 100 mm and above, butterfly valves are either two position or modulating, and they are less expensive than globe-style valves (see Chapter 46 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* for information on globe valves).

A **ball valve** consists of a ball with a hole drilled through it, rotating in a valve body. Ball valves are increasingly popular because of their low cost and high close-off ratings. Features that provide flow characteristics similar to or better than globe valves are available.

Pressure-independent valves are control valves with integral pressure regulators. This allows the valve to maintain a constant flow at a given shaft position because the integral pressure regulator maintains a constant differential pressure across the valve's orifice, regardless of system pressure fluctuations.

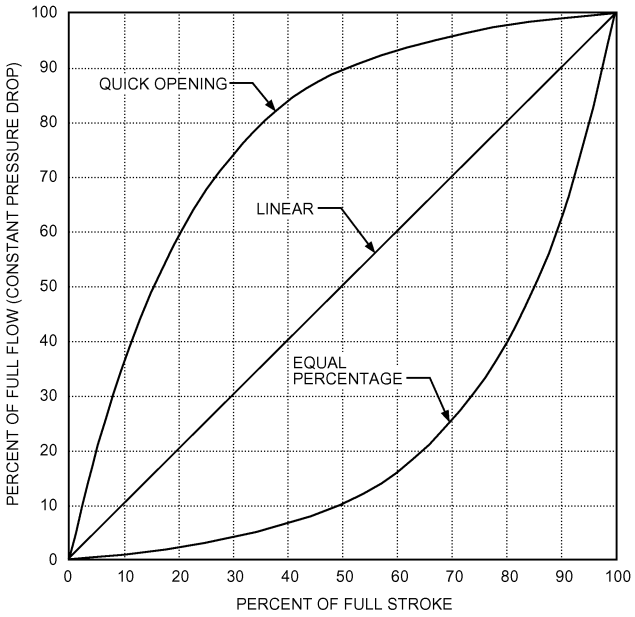

Fig. 10 Typical Flow Characteristics of Valves

Flow Characteristics. Valve performance is expressed in terms of its flow characteristics as it operates through its stroke, based on a constant pressure drop. Three common characteristics are shown in Figure 10 and are defined as follows:

- **Quick opening.** Maximum flow is approached rapidly as the device begins to open.
- **Linear.** Opening and flow are related in direct proportion.
- **Equal percentage.** Each equal increment of opening increases flow by an equal percentage over the previous value.

On a pressure-dependent valve, because pressure drop across the valve's orifice seldom remains constant as its opening changes, actual performance usually deviates from the published characteristic curve. The magnitude of deviation is determined by the overall design. For example, in a system arranged so that control valves or dampers can shut off all flow, pressure drop across a controlled device increases from a minimum at design conditions to total pressure drop at no flow. Figure 11 shows the extent of resulting deviations for a valve or damper designed with a linear characteristic, when selection is based on various percentages of total system pressure drop. To allow for adequate control by the valve, design pressure drop should be a reasonably large percentage of total system pressure drop at the valve (i.e., adequate valve authority) and the system should be designed and controlled so that pressure drop remains relatively constant. Hydronic piping circuits and valve authority are discussed in Chapters 13 and 46 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*, respectively.

Selection and Sizing. Higher pressure drops for control devices are obtained by using smaller sizes, with a possible increase in size of other equipment in the system. Sizing control valves is discussed in Chapter 46 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

Steam Valves. Steam-to-water and steam-to-air heat exchangers are typically controlled by regulating steam flow using a two-way throttling valve. One-pipe steam systems require a line-size, two-position valve for proper condensate drainage and steam flow; two-pipe steam systems can be controlled by two-position or modulating (throttling) valves. Maximum pressure drop for steam valves is a function of operating pressure and cannot be exceeded.

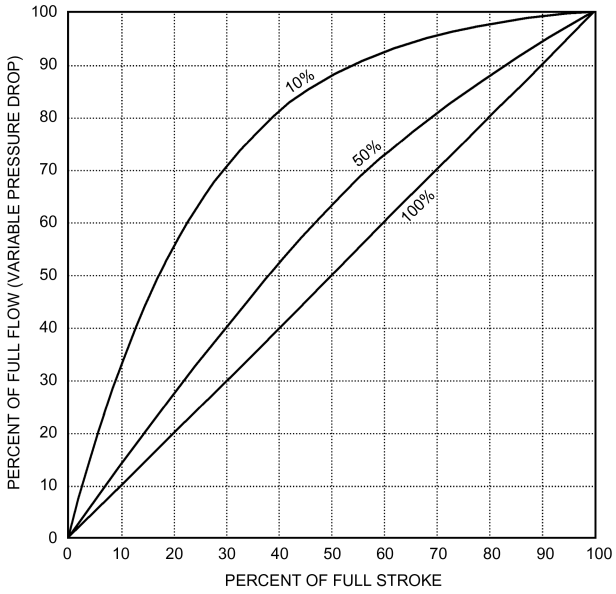

Fig. 11 Typical Valve Authority Performance Curves for Linear Devices at Various Percentages of Total System Pressure Drop

Water Valves. Valves for water service may be two- or three-way and two-position or proportional. Proportional valves are used most often, but two-position valves are not unusual and are sometimes essential. Variable-flow systems are designed to keep the pressure differential constant from supply to return. For valve selection, it is safer to assume that the pressure drop across the valve increases as it modulates from fully open to fully closed.

Equal-percentage valves provide better control at part load, particularly in hot-water coils because the coil's heat output is not linearly related to flow. As flow reduces, more heat is transferred with each unit of water, counteracting the reduction in flow. Equal-percentage valves can provide linear heat transfer from the coil with respect to the control signal.

Actuators. Valve actuators include the following general types:

- A **pneumatic valve actuator** consists of a spring-opposed, flexible diaphragm or bellows attached to the valve stem. An increase in air pressure above the minimum point of the spring range compresses the spring and simultaneously moves the valve stem. Springs of various pressure ranges can sequence the operation of two or more devices, if properly selected or adjusted. For example, a chilled-water valve actuator may modulate the valve from fully closed to fully open over a spring range of 60 to 90 kPa (gage), whereas a sequenced steam valve may actuate from 20 to 55 kPa (gage).

  Two-position pneumatic control is accomplished using a two-position pneumatic relay to apply either full air pressure or no pressure to the valve actuator. Pneumatic valves and valves with spring-return electric actuators can be classified as normally open or normally closed.

  A **normally open valve** assumes an open position, providing full flow, when all actuating force is removed.

  A **normally closed valve** assumes a closed position, stopping flow, when all actuating force is removed.

- **Double-acting** or **springless pneumatic valve actuators**, which use two opposed diaphragms or two sides of a single diaphragm, are generally limited to special applications involving large valves or high fluid pressure.

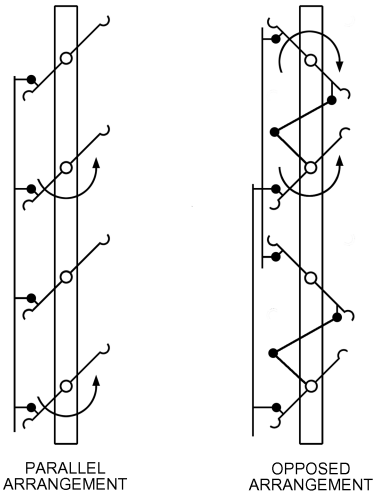

Fig. 12 Typical Multiblade Dampers

- An **electric-hydraulic valve actuator** is similar to a pneumatic one, except that it uses an incompressible fluid circulated by an internal electric pump.
- A **thermostatic valve actuator** uses the volume change with temperature of a substance in a sealed chamber to move a diaphragm, which in turn moves the valve shaft. These actuators can be used as two-position or modulating. In **wax thermostatic valves,** the volume change is caused by phase change (the wax melts or solidifies). The heat source is usually the environment or the fluid whose temperature is being controlled, but can also be a resistive element in the chamber receiving voltage from a controller.
- A **solenoid** consists of a magnetic coil operating a movable plunger. Most are for two-position operation, but modulating solenoid valves are available with a pressure equalization bellows or piston to achieve modulation. Solenoid valves are generally limited to relatively small sizes (up to 100 mm).
- An **electric actuator** operates the valve stem through a gear train and linkage. Electric motor actuators are classified in the following three types:
  - **Spring-return**, for two-position operation (energy drives the valve to one position and a spring returns the valve to its normal position) or for modulating operation (energy drives the valve to a variable position and a spring returns the valve to an open or closed position upon a signal or power failure). With spring-return electric actuators, on loss of actuator power, the spring positions the valve to its fail-safe (normal) position (either fully open or fully closed).
  - **Electronic fail-safe,** which uses a capacitor instead of a spring to drive the actuator to its fail-safe (normal) position. The fail-safe position can be set for fully open, fully closed, or anywhere in between at varying increments.
  - **Reversible**, for floating and proportional operation. The motor can run in either direction and can stop in any position. It is sometimes equipped with a return spring or an electronic fail-safe. In proportional-control applications, an integral feedback potentiometer for rebalancing the control circuit is also driven by the motor.

Dampers

Automatic dampers are used in air conditioning and ventilation to control airflow. They may be used (1) in a modulating application to maintain a controlled variable, such as mixed air temperature or

Licensed for single user. © 2021 ASHRAE, Inc.

supply air duct static pressure; or (2) for two-position control to initiate operation, such as opening minimum outdoor air dampers when a fan is started.

Multiblade dampers are typically available in two arrangements: parallel-blade and opposed-blade (Figure 12), although combinations of the two are manufactured. They are used to control flow through large openings typical of those in air handlers. Both types are adequate for two-position control.

When dampers are applied in modulating control loops, a nonlinear relationship between flow and stroke can lead to difficulties in tuning a control loop for performance. Nonlinearity is expressed as variation in the slope of the flow versus stroke curve. Perfect linearity is not required: if slope varies throughout the range of required flow by less than a factor of 2 from the slope at the point where the loop is tuned, nonlinearity is not likely to disrupt performance.

Parallel blades are used for modulating control when the design condition pressure drop of the damper is about 25% or more of the pressure in a subsystem (Figure 13A). **Opposed-blade dampers** are preferable for modulating control when the damper is about 15% or less of the pressure drop in a subsystem (Figure 13B). A subsystem is defined as a portion of the duct system between two relatively constant pressure points (e.g., the return air section between the mixed air and return plenum tee). A combination may be considered between 15 and 25% damper drop. **Single-blade dampers** are typically used for flow control in small terminal units.

In Figure 13, *A* is **authority**, which is the ratio of pressure drop across the fully open damper at design flow to total subsystem pressure drop, including fully open control damper pressure drop. The curves here are typical for ducted applications. The Air Movement and Control Association (AMCA *Standard* 500) defined a number of geometric arrangements of dampers for testing pressure losses. The curves in Figure 13 are those of an AMCA 5.3 geometry, which is a fully ducted arrangement with long sections of duct before and after a damper. Other geometric applications, such as plenum or wall-mounted dampers, exhibit different response curves (Felker and Felker 2009; van Becelaere et al. 2004).

Figure 14 shows two parallel-blade (PB) applications, two opposed-blade (OB) applications, and an "anti-PB" (aPB) arrangement. The response curves are not like those of the AMCA 5.3

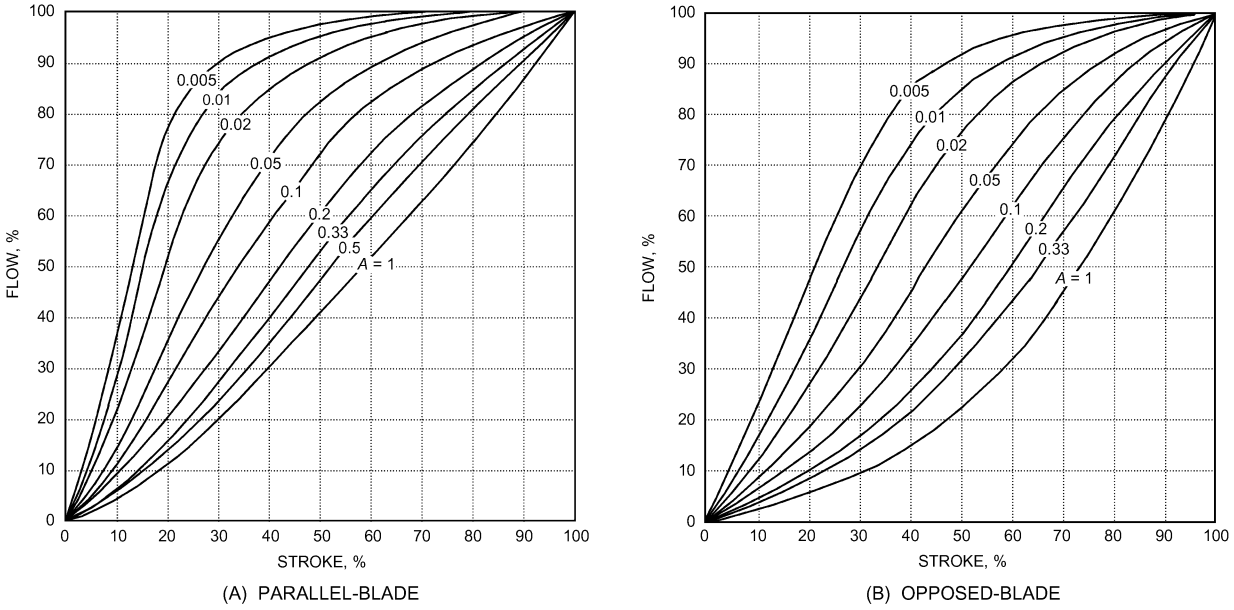

Fig. 13 Characteristic Curves of Installed Dampers in an AMCA 5.3 Geometry

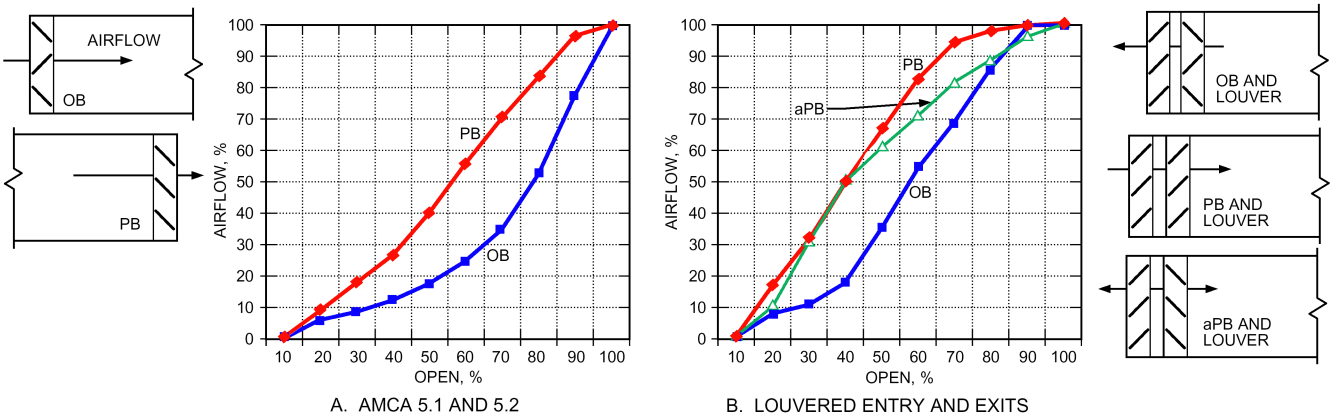

Fig. 14 Inherent Curves for Partially Ducted and Louvered Dampers (RP-1157)
Based on data in van Becelaere et al. (2004)

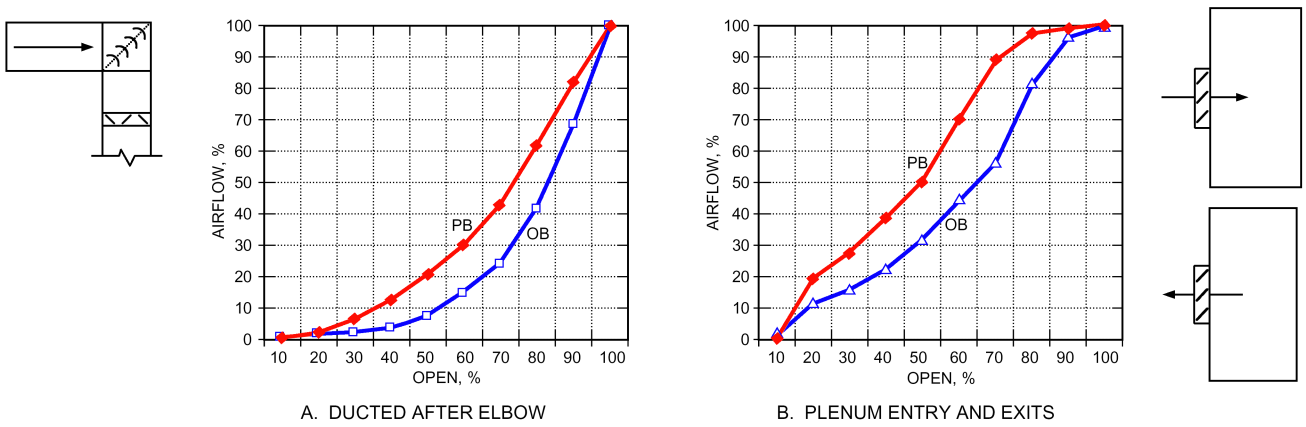

Fig. 15 Inherent Curves for Ducted and Plenum-Mounted Dampers (RP-1157)
Based on data in van Becelaere et al. (2004)

ducted application. These are "inherent" curves, where pressure drop across a damper is held constant as the damper rotates (so it has 100% authority). In real applications, the authority is lower (higher losses of other system components besides the damper). As system pressure losses increase, the curves move up. Note that PB dampers are significantly above linear in most cases.

Figure 15 shows three more applications with PB and OB dampers. The ducted damper has some disturbance and pressure loss ahead of it, to simulate a more realistic situation than those of AMCA 5.3. Nevertheless, the response curves are similar to AMCA 5.3. The plenum entry dampers show irregular results. Again, these are inherent curves, and lower authority causes the curves to move up toward more flow at smaller angles.

The curves shown here are typical, but do not represent every scenario. Thousands of installation variations exist, and slight variations in response always occur. For additional application examples and greater detail, see ASHRAE research project RP-1157 (van Becelaere et al. 2004).

Application. Dampers require engineering to achieve defined goals. A common application is a flow control damper, which modulates airflow. The curves in Figure 13 can be used to pick a damper with a pressure drop and authority that provides near-linear response. Another common application is economizer outdoor air, return air, and exhaust air dampers. Selection of these dampers depends on the system design, as discussed in ASHRAE *Guideline* 16-2014.

Damper leakage is a concern, particularly where tight shutoff is necessary to significantly reduce energy consumption. Also, outdoor air dampers in cold climates must close tightly to prevent coils and pipes from freezing. Low-leakage dampers cost more and require larger actuators because of friction of the seals in the closed position; however, the energy savings offset the extra cost.

Actuators. Either electricity or compressed air is used to actuate dampers.

Pneumatic damper actuators are similar to pneumatic valve actuators, except that they have a longer stroke or the stroke is increased by a multiplying lever. Increasing air pressure produces a linear shaft motion, which, through a linkage, moves the crank arm to open or close the dampers. Releasing air pressure allows a spring to return the actuator. Double-acting actuators without springs are available also.

Electric damper actuators can be proportional or two-position. They can be spring return or nonspring. The simplest form of control is a floating three-point controller, in which contact closures drive the motor clockwise or counterclockwise. In addition, a variety of standard electronic signals from electronic controllers or DDC systems, such as 4 to 20 mA, 2 to 10 V (dc), or 0 to 10 V (dc), can be used to control proportionally actuated dampers.

Most modern actuators are electronic and use more sophisticated methods of control and operation. They are inherently positive positioning and may have communications capabilities similar to industrial-process-quality actuators.

A two-position spring-return actuator moves in one direction when power is applied to its internal windings. When no power is present, the actuator returns (via spring force) to its fail-safe (normal) position. Depending on how the actuator is connected, this action opens or closes the dampers. A proportional actuator may also have spring-return action.

Mounting. Damper actuators are mounted in different ways, depending on the size and accessibility of the damper, and the power required to move the damper. The most common method of mounting electric actuators is directly over the damper shaft (direct coupling) with no external linkage. Actuators can also be mounted in the airflow on the damper frame and be linked directly to a damper blade (though this may deform blades and make access for repairs difficult), or mounted outside the duct and connected to a crank arm attached to a shaft extension of one of the blades. Mounting methods that link the actuator to a single blade are not recommended because of the potential to bend the single drive blade or to have the blade-to-blade linkages get out of adjustment.

Large dampers may require two or more actuators, which are usually mounted at separate points on the damper. An alternative is to install the damper in two or more sections, each section being controlled by a single damper actuator. Positive positioners may be required for proper sequencing, as with a small damper controlled to maintain healthy indoor air quality, with a large damper being independently controlled for economy-cycle free cooling.

Pneumatic Positive (Pilot) Positioners

Where accurate positioning of a modulating pneumatic damper or valve is required, use positive positioners. A positive positioner provides up to full supply control air pressure to the actuator for any change in position required by the controller. A pneumatic actuator without a positioner may not respond quickly or accurately enough to small changes in control pressure caused by friction in the actuator or load, or to changing load conditions such as wind acting on a damper blade. A positive positioner provides finite and repeatable positioning change and allows adjustment of the control range (spring range of the actuator) to provide a proper sequencing control of two or more control devices.

2.2 SENSORS AND TRANSMITTERS

A sensor responds to a change in the controlled variable. The response, which is a change in some physical or electrical property of the primary sensing element, is available for translation or amplification into a mechanical or electrical signal. This signal is sent to the controller.

Transmitters take the output of a sensor and convert the sensor's signal to an industry-standard signal type (e.g., 4 to 20 mA, 0 to 10 V, network protocol).

Chapter 48 of the 2019 *ASHRAE Handbook—HVAC Applications* and manufacturer's catalogs and tutorials include information on specific applications. In selecting a sensor for a specific application, consider the following:

- **Operating range of controlled variable.** The sensor must be capable of providing an adequate change in its output signal over the expected input range.
- **Compatibility of controller input.** Electronic and digital controllers accept various ranges and types of electronic signals. The sensor's signal must be compatible with the controller. If the controller's input requirements are unknown, it may be possible to use a transducer to convert the sensor signal to an industry-standard signal, such as 4 to 20 mA or 0 to 10 V (DC).
- **Accuracy, sensitivity, and repeatability.** For some control applications, the controlled variable must be maintained within a narrow band around a desired set point. Both the accuracy and sensitivity of the sensor selected must reflect this requirement. **Sensitivity** is the ratio of a change in output magnitude to the change of input that causes it, after steady state has been reached. **Repeatability** is closeness of agreement among repeated measurements of the same variable under the same conditions. However, even an accurate sensor cannot maintain the set point if (1) the controller is unable to resolve the input signal, (2) the controlled device cannot be positioned accurately, (3) the controlled device exhibits excessive hysteresis, or (4) disturbances drive its system faster than the controls can regulate it. See ASHRAE *Guideline* 13, clause 7.9, for a discussion on end-to-end accuracy.
- **Sensor response time.** Associated with a sensor/transducer arrangement is a response curve, which describes the response of the sensor output to change in the controlled variable. If the time constant of the process being controlled is short and stable and accurate control is important, then the sensor selected must have a fast response time.
- **Control agent properties and characteristics.** The control agent is the medium to which the sensor is exposed, or with which it comes in contact, for measuring a controlled variable such as temperature or pressure. If the agent corrodes the sensor or otherwise degrades its performance, a different sensor should be selected, or the sensor must be isolated or protected from direct contact with the control agent.
- **Ambient environment characteristics.** Even when the sensor's components are isolated from direct contact with the control agent, the ambient environment must be considered. The temperature and humidity range of the ambient environment must not reduce the sensor's accuracy. Likewise, the presence of certain gases, chemicals, and electromagnetic interference (EMI) can cause performance degradation. In such cases, a special sensor or transducer housing can be used to protect it. Special housings may also be required in wet, flammable, explosive, or corrosive environments.
- **Placement requirements.** The sensing element must be in the correct point(s) required for proper measurement. For instance, pipe wall thickness (schedule) affects the required length of water temperature or flow probes; sensors inside air ducts (especially low-temperature switches) should be long enough to compensate for air stratification; room temperature and humidity sensors should not be installed close to heat sources, on outer walls, in direct airstreams, or in areas where air stalls (e.g., behind furniture); single measurements of return air properties, no matter how accurate, are just averages and do not detect areas with simultaneous opposite extremes.

Temperature Sensors

Temperature-sensing elements generally detect changes in either (1) relative dimension (caused by differences in thermal expansion), (2) the state of a vapor or liquid, or (3) some electrical property. Within each category, there are various sensing elements to measure room, duct, water, and surface temperatures. Temperature-sensing technologies commonly used in HVAC applications are as follows:

- A **bimetal element** is composed of two thin strips of dissimilar metals fused together. Because the two metals have different coefficients of thermal expansion, the element bends and changes position as the temperature varies. Depending on the space available and the movement required, it may be straight, U-shaped, or wound into a spiral. This element is commonly used in room, insertion, and immersion thermostats.
- A **rod-and-tube element** consists of a high-expansion metal tube containing a low-expansion rod. One end of the rod is attached to the rear of the tube. The tube changes length with changes in temperature, causing the free end of the rod to move. This element is commonly used in certain insertion and immersion thermostats.
- A **sealed bellows element** is either vapor, gas, or liquid filled. Temperature changes vary the pressure and volume of the gas or liquid, resulting in a change in force or a movement.
- A **remote bulb element** is a bulb or capsule connected to a sealed bellows or diaphragm by a capillary tube; the entire system is filled with vapor, gas, or liquid. Temperature changes at the bulb cause volume or pressure changes that are conveyed to the bellows or diaphragm through the capillary tube. This element is useful where the temperature-measuring point is remote from the desired thermostat location.
- A **thermistor** is a semiconductor that changes electrical resistance with temperature. It has a negative temperature coefficient (i.e., resistance decreases as temperature increases). Its characteristic curve of temperature versus resistance is nonlinear over a wide range. Several techniques are used to convert its response to a linear change over a particular temperature range. With digital control, one technique is to store a computer look-up table that maps the temperature corresponding to the measured resistance. The table breaks the curve into small segments, and each segment is assumed to be linear over its range. Thermistors are used because of their relatively low cost, the large change in resistance possible for a small change in temperature, and their long-term stability.
- A **resistance temperature device (RTD)** also changes resistance with temperature. Most metallic materials increase in resistance with increasing temperature; over limited ranges, this variation is linear for certain metals (e.g., platinum, copper, tungsten, nickel/iron alloys). Platinum, for example, is linear within ±0.3% from –18 to 150°C. The RTD sensing element is available in several forms for surface or immersion mounting. Flat grid windings are used for measurements of surface temperatures. For direct measurement of fluid temperatures, the windings are encased in a stainless steel bulb to protect them from corrosion.

Humidity Sensors and Transmitters

Humidity sensors, or **hygrometers**, measure relative humidity, dew point, or absolute humidity of ambient or moving air. **Transmitters** convert the signal from the humidity sensor to an industry-standard output such as 0 to 10 V or 4 to 20 mA. Some transmitters compensate for temperature variations. Two types of sensors that

Licensed for single user. © 2021 ASHRAE, Inc.

detect relative humidity are mechanical hygrometers and electronic hygrometers.

Electronic hygrometers can use either resistance or capacitance sensing elements. The resistance element is a conductive grid coated with a hygroscopic substance. The grid's conductivity varies with the water retained; thus, resistance varies with relative humidity. The conductive element is arranged in an AC-excited Wheatstone bridge and responds rapidly to humidity changes.

The capacitance element is a stretched membrane of nonconductive film, coated on both sides with metal electrodes and mounted in a perforated plastic capsule. The response of the sensor's capacity to rising relative humidity is nonlinear. The signal is linearized and temperature is compensated in the amplifier circuit to provide an output signal as relative humidity changes from 0 to 100%.

The **chilled-mirror humidity sensor** determines dew point rather than relative humidity. Air flows across a small mirror in the sensor. A thermoelectric cooler lowers the surface temperature of the mirror until it reaches the dew point of the air. Condensation on the surface reduces the amount of light reflected from the mirror compared to a reference light level.

Dispersive infrared (DIR) technology can be used to sense absolute humidity or dew point. It is similar to technology used to sense carbon dioxide or other gases. Infrared water vapor sensors are optical sensors that detect the amount of water vapor in air based on the infrared light absorption characteristics of water molecules. Light absorption is proportional to the number of molecules present. An **infrared hygrometer** typically provides a value of absolute humidity or dew point, and can operate in diffusion or flow-through sample mode. This type of humidity sensor is unique in that the sensing element (a light detector and an infrared filter) is behind a transparent window and is never exposed directly to the sample environment. As a result, this sensor has excellent long-term stability, long life, and fast response time; is not subject to saturation; and operates equally well in very high or low humidity. Previously used solely for high-end applications, infrared hygrometers are now commonly used in HVAC applications because they cost about the same as mid-range-accuracy (1 to 3%) humidity sensors.

Pressure Transmitters and Transducers

A pneumatic pressure transmitter converts a change in absolute, gage, or differential pressure to a mechanical motion using a bellows, diaphragm, or Bourdon tube mechanism. When connected through appropriate links, this mechanical motion produces a change in air pressure to a controller. In some instances, sensing and control functions are combined in a single component, a pressure controller.

An electronic pressure transducer may use mechanical actuation of a diaphragm or Bourdon tube to operate a potentiometer or differential transformer. Another type uses a strain gage bonded to a diaphragm. The strain gage detects displacement resulting from the force applied to the diaphragm. Capacitance transducers are most often used for measurements below 250 Pa because of their high sensitivity and repeatability. Electronic circuits provide temperature compensation and amplification to produce a standard output signal.

Flow Rate Sensors

Orifice plate, pitot-static tube, venturi, turbine, magnetic flow, thermal dispersion, vortex shedding, and ultrasonic meters are some of the technologies used to sense fluid flow. In general, pressure differential devices (orifice plates, venturi, and pitot tubes) are less expensive and simpler to use, but have limited range; thus, their accuracy depends on how they are applied and where in a system they are located.

More sophisticated flow devices, such as turbine, magnetic, and vortex shedding meters, usually have better range and are more accurate over a wide range. If an existing piping system is being considered for retrofit with a flow device, the expense of shutting down the system and cutting into a pipe must be considered. In this case, a noninvasive meter, such as an ultrasonic flow meter, may be cost effective.

There are two types of ultrasonic flow meters. One uses the Doppler effect, which is better for monitoring flow in slurry applications. The other type uses the transit time effect, which is more accurate at lower flows and with standard nonslurry fluids.

For air velocity metering, pitot-static tubes provide a naturally larger signal change at high velocities, with limitations on their application below 2.5 to 3 m/s. Vortex shedding for airflow applications has similar low-velocity limitations. Thermal dispersion sensors provide a naturally larger signal change at lower velocities without appreciable losses through velocities common in most ventilation systems, which makes them more suitable for applications below 5 m/s.

Indoor Air Quality Sensors

Indoor air quality control can be divided into two categories: ventilation control and contamination protection. In spaces with dense populations and intermittent or highly variable occupancy, ventilation can be more efficiently applied by detecting changes in population or ventilation requirements [**demand-controlled ventilation (DCV)**]. This involves using time schedules and population counters, and measuring the indoor/outdoor differential levels of carbon dioxide (CO_2) or other contaminants in a space. Changes in differential CO_2 mirror changes in space population; thus, the amount of outdoor air introduced into the occupied space can then be controlled. Demand control helps maintain proper ventilation rates at all levels of occupancy. Control set-point levels for carbon dioxide are determined by the specific relationships between differential CO_2, rate of CO_2 production by occupants, the variable airflow rate required by the changing population, and a fixed amount of ventilation required to dilute building-generated contaminants unrelated to CO_2 production. ASHRAE *Standard* 62.1 and its user's manual (ASHRAE 2013) provide further information on ventilation for acceptable indoor air quality and DCV for single-zone systems.

Contamination protection sensors monitor levels of hazardous or toxic substances and issue warning signals and/or initiate corrective actions through the building automation system (BAS). Sensors are available for many different gases. The carbon monoxide (CO) sensor is one of the most common, and is often used in buildings wherever combustion occurs (e.g., parking garages). Refrigerant-specific sensors are used to measure, alarm, and initiate ventilation purging in enclosed spaces that house refrigeration equipment, to prevent occupant suffocation upon a refrigerant leak (see ASHRAE *Standard* 15 for more information). The type selected, substances monitored, and action taken in an alarm condition all depend on where these sensors are applied.

Lighting Level Sensors

Analog lighting level transmitters packaged in various configurations allow control of ambient lighting levels using building automation strategies for energy conservation. Examples include ceiling-mounted indoor light sensors used to measure room lighting levels; outdoor ambient lighting sensors used to control parking, general exterior, security, and sign lighting; and interior skylight sensors used to monitor and control light levels in skylight wells and other atrium spaces.

Power Sensing and Transmission

Passive electronic devices that sense the magnetic field around a conductor carrying current allow low-cost instrumentation of power circuits. A wire in the sensor forms an inductive coupling that powers the internal function and senses the level of the power signal. These devices can provide an analog output signal to monitor

Licensed for single user. © 2021 ASHRAE, Inc.

current flow or operate a switch at a user-set level to turn on an alarm or other device.

2.3 CONTROLLERS

An HVAC controller reads sensors' signals and regulates control devices to achieve one or more objectives, which may include maintaining comfort, minimizing energy use, and ensuring safe operation and environmental conditions. Controllers can use other sources of information to determine their output, such as schedules, tables, operator commands, and weather forecasts. Controllers may also collect data about the processes and their own operation to help monitor, diagnose, and tune the processes' operation. Digital controllers perform the control functions using a microprocessor and control algorithms. The sensors and controller can be combined in a single instrument, such as a room thermostat, or they may be separate devices.

Digital Controllers

Digital controls use microprocessors to execute software programs that are customized for use in commercial buildings. Controllers use sensors to measure values such as temperature and humidity, perform control routines in software programs, and exert control using output signals to actuators such as valves and electric or pneumatic actuators connected to dampers. The operator may enter parameters such as set points, proportional or integral gains, minimum on and off times, or high and low limits, but the control algorithms make the control decisions. The controller scans input devices, executes control algorithms, and then positions the output device(s), in a stepwise scheme. The controller calculates proper control signals digitally rather than using an analog circuit or mechanical change, as in electric/electronic and pneumatic controllers. Use of digital controls in building automation is referred to as direct digital control (DDC).

Digital controls can be used as stand-alones or can be integrated into building management systems (BMSs) through network communications. Simple controls may have a single control loop that can perform a single control function (e.g., temperature control of a unit ventilator); larger versions can control a larger number of loops or even perform complex strategies such as managing energy allocation to multiple processes and open loop controls, and balancing multiple objectives (e.g., comfort, energy consumption, equipment wear).

Advantages of digital controls include the following:

- Sequences or equipment can be modified by changing software, which reduces the cost and diversity of hardware necessary to achieve control.
- Features such as demand setback, reset, data logging, diagnostics, and time-clock integration can be added to the controller with small incremental cost.
- Precise, accurate control can be implemented, limited by the resolution of sensor and analog-to-digital (A/D) and digital-to-analog (D/A) conversion processes. PID and other control algorithms can be implemented mathematically and can adjust performance based on sophisticated algorithms.
- Controllers can communicate with each other using open or proprietary networking (e.g., Ethernet or RS-485) standards.

A single control that is fixed in functionality with flexibility to change set points and small configurations is called an **application-specific controller**. Many manufacturers include application-specific controls with their HVAC equipment, such as air-handling units and chillers.

Firmware and Software. Preprogrammed control routines, known as firmware, are sometimes stored in permanent memory such as programmable read-only memory (PROM) or electrically programmable read-only memory (EPROM), and the application or set points are stored in changeable memory such as electrically erasable programmable read-only memory (EEPROM). The operator can modify parameters such as set points, limits, and minimum *off* times within the control routines, but the primary program logic cannot be changed without replacing the memory chips.

User-programmable controllers allow the algorithms to be changed by the user. The programming language provided with the controller can vary from a derivation of a standard language to custom language developed by the controller's manufacturer, to graphically based programming. Preprogrammed routines for proportional, proportional plus integral, Boolean logic, timers, etc., are typically included in the language. Standard energy management routines may also be preprogrammed and may interact with other control loops where appropriate.

Digital controllers can have both preprogrammed firmware and user-programmed routines. These routines can automatically modify the firmware's parameters according to user-defined conditions to accomplish the control sequence designed by the control engineer.

Operator Interface. Some digital controllers (e.g., a programmable room thermostat) are designed for dedicated purposes and are adjustable only through manual switches and potentiometers mounted on the controller. This type of controller cannot be networked with other controllers. A **direct digital controller** can have manually adjustable features, but it is more typically adjusted either through a built-in LED or LCD display, a hand-held device, or a terminal or computer. The direct digital controller's digital communication allows remote connection to other controllers and to higher-level computing devices and host operating stations.

A **terminal** allows the user to communicate with the controller and, where applicable, to modify the program in the controller. Terminals can range from hand-held units with an LCD display and several buttons to a full-sized console with a video monitor and keyboard. The terminal can be limited in function to allow only display of sensor and parameter values, or powerful enough to allow changing or reprogramming the control strategies. In some instances, a terminal can communicate remotely with one or more controllers, thus allowing central displays, alarms, and commands. Usually, hand-held terminals are used by technicians for troubleshooting, and full-sized, fully functional terminals are used at a fixed location to monitor the entire digital control system. Standard Internet browsers can sometimes be used to access system information, complemented with online help and application libraries, plus cloud-based troubleshooting and graphic user interface design tools.

Electric/Electronic Controllers

For **two-position control**, the controller output may be a simple electrical contact that starts a fan or pump, or one that actuates a spring-return valve or damper actuator. Electrical contacts can be normally open (NO), normally closed (NC), or have one of each (double throw). An output that has three terminals (common, NO, and NC) is called single-pole, double-throw (SPDT). SPDTs simplify designs, because the same device can be used as NO or NC depending on the requirements of the application. In some cases, both contacts are used (e.g., to send a signal to one device or another, depending on whether the system is in cooling or heating mode). Both single-pole, single-throw (SPST) and SPDT circuits can be used for timed two-position action.

Floating control uses two NO output contacts with a neutral zone where neither contact is made. This control is used with reversible motors; it has a slow response and a wide throttling range.

Output for **floating control** is a SPDT switching circuit with a neutral zone where neither contact is made. This control is used with reversible motors; it has a slow response and a wide throttling range.

Licensed for single user. © 2021 ASHRAE, Inc.

Pulse modulation control is an improvement over floating control. It provides closer control by varying the duration of the contact closure. As the actual condition moves closer to the set point, the pulse duration shortens for closer control. As the actual condition moves farther from the set point, the pulse duration lengthens.

Proportional control gives continuous or incremental changes in output signal to position an electrical actuator or controlled device.

Pneumatic Receiver-Controllers

Pneumatic receiver-controllers are normally combined with pneumatic elements that use a mechanical force or position reaction to the sensed variable to obtain a variable-output air pressure. Control is usually proportional, but other modes (e.g., proportional-plus-integral) can be used. These controllers are generally classified as nonrelay or relay, and as direct-acting or reverse-acting.

The nonrelay (single-pipe) pneumatic controller uses low-volume output. A relay (two-pipe) pneumatic controller actuates a relay device that amplifies the air volume available for control. The relay provides quicker response to a variable change.

Direct-acting controllers increase the output signal as the controlled variable increases. Reverse-acting controllers increase the output signal as the controlled variable decreases. For example, a reverse-acting pneumatic thermostat increases output pressure when the measured temperature drops and decreases output pressure when the measured temperature rises.

Thermostats

Thermostats combine sensing and control functions in a single device. Microprocessor-based thermostats have many of the following features.

- An **occupied/unoccupied** or **dual-temperature room thermostat** controls at another set-point temperature at night. It may be indexed (changed from occupied to unoccupied) individually or in a group by a manual switch, an electronic occupancy sensor, or time switch from a remote point. Some electric units have an individual clock and switch built into the thermostat.
- A **pneumatic day/night thermostat** uses a two-pressure air supply system [often 90 and 120 kPa (gage), or 100 and 140 kPa (gage)]. Changing pressure at a central point from one value to the other actuates switching devices in the thermostat that index it from occupied to unoccupied or vice versa.
- A **heating/cooling** or **summer/winter thermostat** can have its action reversed and its set point changed by indexing. It is used to actuate control devices (e.g., valves, dampers) that regulate a heating source at one time and a cooling source at another.
- A **multistage thermostat** operates two or more successive steps in sequence.
- A **submaster thermostat** has its set point raised or lowered over a predetermined range in accordance with variations in output from a master controller. The master controller can be a thermostat, manual switch, pressure controller, or similar device.
- A **dead-band thermostat** has a wide differential over which the thermostat remains neutral, requiring neither heating nor cooling. This differential may be adjustable up to 6 K. The thermostat then controls to maximum or minimum output over a small differential at the end of each dead band (Figure 16).

2.4 AUXILIARY CONTROL DEVICES

Auxiliary control devices for electric systems include the following:

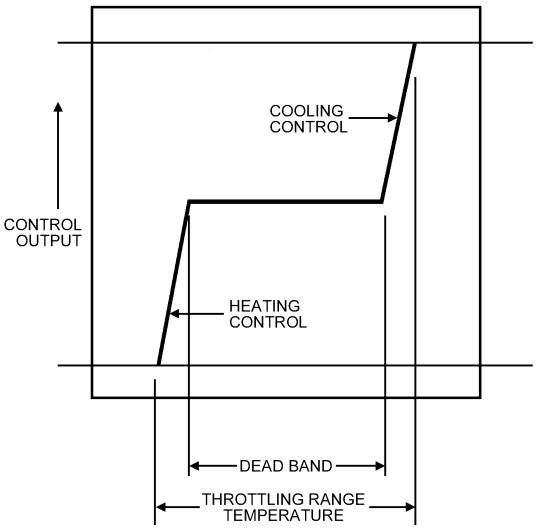

Fig. 16 Dead-Band Thermostat

Relays

Relays provide a means for one electrical source to switch to a different electrical circuit. The switched voltage may be the same or different. Relay configurations include several variations:

- Shape and number of electrical connections
- Optional override button and/or LED indication
- Base or panel mount
- Electromechanical or solid state
- Normally open or normally closed (or both)
- Latching or nonlatching

Electric relays can be used to start and stop electric heaters, burners, compressors, fans, pumps, or other apparatus for which the electrical load is too large to be handled directly by the controller. Other uses include time-delay and circuit-interlocking safety applications. Form letters are part of an industry consensus that defines the arrangement of contacts for relays and switches. The three most common types in HVAC are forms A, B, and C. Form A relays are single pole, single throw, normally open (SPST-NO). Form B relays are single pole, single throw, normally closed (SPST-NC). Form C relays are single pole, double throw (SPDT) and can be either normally open or normally closed, so control panels can be built using all form C (SPDT) relays. In small sizes, the added cost of the second contact is insignificant. As current ratings go up, forms A and B become more cost effective.

Time-delay relays, similar to control relays, include an adjustable time delay that is set using dipswitches and/or a knob. The device is either a delay-on-make (*on* delay) or delay-on-break (*off* delay). The time delay is either in seconds to minutes or minutes to hours. Uses include preventing multiple pieces of equipment from starting simultaneously and overloading the electrical supply, ensuring equipment completes its warm-up cycle, preventing triggering of nuisance alarms during short transitions (e.g., before equipment has reached enough speed for its status sensors to activate), and temporarily changing the mode of operation (e.g., thermostat override timer during unoccupied hours).

Power relays handle high-power switching of electrical loads in motor control centers and lighting control applications. They may be of open-frame construction or enclosed, single or multiple pole, panel mounted or field mounted, with or without auxiliary contacts.

Solid-state relays are optically isolated relays used to switch voltages up to 600 V with high amperage loads using a form A

Licensed for single user. © 2021 ASHRAE, Inc.

contact. They have a high surge dielectric strength, and reverse voltage protection. They operate using an input voltage of 4 to 32 V DC. These devices are easily affected by high temperatures and induced currents, but their life expectancy, measured in number of operations, is much greater than that of electromechanical switches, so they are used wherever switching every few minutes or seconds is required, as in pulse-width modulation (PWM) controls.

Control relay sockets are used with control relays to terminate all the wires that need to be connected to the relay. They may have either blade- or pin-type terminals. Sockets make wiring easier (without the relay getting in the way), provide a way to ensure equipment is not started until the system is commissioned, and allow relay replacement without redoing the wiring terminations.

Equipment Status

Auxiliary contacts are sometimes used to determine equipment status. The auxiliary contacts close when the starter's contactor closes, so they do not account for broken belts, couplings, or wires; locked rotors; flow obstructions; or missing power.

Differential pressure switches are used for status indication for air filters, fans, and pumps. Additionally, they can be used to provide flow and level status and in safety circuits to protect system components.

Current switches are current-sensing relays used to monitor the status of electrical devices. Typically, they have one or more adjustable current set points. They should be adjusted at start-up so that if the fan or pump motor coupling breaks, the current switch does not indicate *on* status.

Paddle switches indicate flow of water or air and are used to sense the status of pumps and fans.

Equipment with embedded controls such as boilers, chillers, terminal units, and variable-speed pumps and fans usually provide their status through contacts and over serial communication.

Limit switches convert mechanical motion into a switching action. Common applications include valve and damper position and proximity feedback.

Other Switches

Manual switches, either two-position or multiple-position with single or multiple poles, are used to switch equipment from one state to another.

Auxiliary switches on electric or electronic equipment, such as valve and damper actuators, sensors, and variable-speed controls are used to select a sequence or mode of operation.

Moisture switches are used to detect moisture in drain pains, under raised floors, and in containment areas to shut down equipment and/or alert operators before flooding or damage occurs.

Level switches (float, conductive probe, or ultrasonic) are used to start/stop equipment, either in normal operation, such as supply or drain pumps, or in protection circuits, as in boilers or chillers.

Time Switches

Time switches (mechanical or electronic) turn electrical loads on and off, based on a 24 h/7 day or 24 h/365 day schedule.

Analog time switches are set manually to control an electrical load. They have either normally open or normally closed contacts. Timing is either in minutes or hours, and may have an override hold feature to keep the load on or off continuously.

Digital time switches are set manually to control an electrical load and have either normally open or normally closed contacts. The timing function is either in minutes or hours, and sometimes combines a regular weekly calendar with a yearly exceptions calendar used for holidays and other special events. They may have an override hold feature to keep the load on or off continuously, and a flash or beeper option to notify the operator that the load will be turning off shortly.

Transducers

Transducers are devices that convert one signal (sensor reading or command) into a signal of another type that conveys some or all of the original information. Examples include pressure into voltage, voltage into current, voltage into contact closure, and rotational speed into pulse frequency. Transducers may convert proportional input to either proportional or two-position output.

The **electronic-to-pneumatic transducer (EPT** is used in many applications. It converts a proportional electronic output signal into a proportional pneumatic signal and can be used to combine electronic and pneumatic control components to form a control loop (Figure 17). Electronic components are used for sensing and signal conditioning, whereas pneumatic components are used for actuation. The electronic controller can be either analog or digital.

The EPT presents a special option for retrofit applications. An existing HVAC system with pneumatic controls can be retrofitted with electronic sensors and controllers while retaining the existing pneumatic actuators (Figure 18).

Signal transducers to change one standard signal into another. Variables usually transformed include voltage [0 to 10, 0 to 5, 2 to 10 V (DC)], current (4 to 20 mA), resistance (0 to 135 Ω), pressure [20 to 100, 0 to 140 kPa (gage)], phase cut voltage [0 to 20 V (DC)], pulse-width modulation, and time duration pulse. Signal transducers allow use of an existing control device in a retrofit application.

Other Auxiliary Control Devices

Variable-frequency drives (VFDs) control AC motors' speed by using electronics to vary the frequency and voltage amplitude of the electrical input power. VFDs are commonly applied to fans, heat recovery wheels, pumps, and compressors.

Occupancy sensors are used to automatically adjust controlled variables (e.g., lighting, ventilation rate, temperature) based on occupancy.

Potentiometers are used for manual positioning of proportional control devices, for remote set-point adjustment of electronic controllers, and for position feedback.

Smoke detectors sense smoke and other combustion products in air moving through HVAC ducts. Through sampling tubes, selected based on duct size, they test air moving in the duct. For duct applications, using only photoelectric sensor heads is recommended. The device typically has two alarm contacts, used to shut down the associated equipment and provide remote indication, and a trouble contact, which monitors incoming power and removal of the detector head. Where a fire alarm system is installed, the smoke detectors must be listed for use with the fire alarm system. Addressable fire alarm systems may use a separate programmable relay for fan shutdown rather than a hard-wired connection to the detector.

Transient voltage surge suppressors (TVSSs), formerly called **lightning arrestors**, protect communication lines and critical power lines between buildings or at building entrance vaults against high-voltage transients caused by VFDs, motors, transmitters, and lightning. To be effective, they must be grounded to a grounding rod in compliance with the National Electrical Code® (NFPA *Standard* 70) or local equivalent, and the manufacturer's recommendations.

Transformers provide current at the required voltage.

Regulated DC power supply devices convert AC voltage into a DC voltage, kept constant independently of the current draw, and usually between 12 and 24 V DC. They may be used to power temperature, pressure, and humidity transmitters.

Fuses are safety devices with a specific amp rating, used with power supplies, circuit boards, control transformers, and transducers. They may be rated for either high or low inrush currents, and are available in slow-blow or fast-acting models.

Step controllers operate several switches in sequence using a proportional electric or pneumatic input signal. They are commonly used to control several steps of heating or refrigeration capacity. They may be arranged to prevent simultaneous starting of compressors and to alternate the sequence to equalize wear.

Power controllers control electric power input to resistance heating elements. They are available with various ratings for single- or three-phase heater loads and are usually arranged to regulate power input to the heater in response to the demands of the proportional electronic or pneumatic controllers. **Silicon controlled rectifiers (SCRs)** are the most common form of power controller used for electric heat. Solid-state controllers in fast-switching two-position control modes are used because they are without mechanical contacts, which wear out too quickly to be of practical use for this application, and can arc when power is applied or removed.

High-temperature limits are safety devices that shut down equipment when the temperature exceeds the high limit set point. They are typically set at 50 to 65°C for heating air applications and 90 to 96°C for hot-water applications. A manual or automatic reset reactivates the device once the condition has cleared.

Low-temperature limits for ducts are used to protect chilled-water and preheat coils from freezing. They typically have a 6 m long vapor-charged sensing element, set at 2°C, that shuts down equipment when the temperature in any 300 or 450 mm section falls below its set point. They may be manually or automatically reset. The device must be mounted parallel to the coil tubes with capillary mounting clips for proper measurement. Limits may be either SPST or double-pole, double-throw (DPDT), with the second contact used to alert operators that the device has tripped.

Three- and **five-valve manifolds** protect water differential pressure sensors from overpressurization during installation, start-up, shutdown, system testing, and maintenance. Three-valve manifolds are comprised of two isolation valves and a bypass valve. A five-valve manifold includes two additional valves to allow online calibration. Depending on the application, snubbers may be required, as well.

Snubbers, made of brass or stainless steel, stop shocks and pulsations caused by fluid hammering and system surges. Two types of pressure snubbers are used in HVAC applications: porous and piston. A porous snubber has no moving parts and uses a porous material to stop device damage. A piston snubber uses a moving piston inside a tube that moves up and down to stop device damage and push away any sediment or scale that may clog the system's monitoring devices. Depending on the application, the type of piston to be used may need to be specified.

Steam pigtail siphons protect pressure transmitters from the high temperature of steam. They are typically made from steel or stainless steel of a specific length with a loop. The temperature of the medium being monitored determines the length and material. Most pressure devices have an operating temperature range of –18 to 95°C.

Thermostat guards are plastic or metal covers that protect switches, thermostat controllers, and sensors from damage, tampering, and unauthorized adjustment.

Enclosures/control panels may be used indoors or outdoors to protect equipment and people. In North America, enclosures are rated by the National Electrical Manufacturers Association (NEMA *Standard* 250) and Electrical and Electronic Manufacturer Association of Canada (EEMAC); elsewhere, they receive an ingress protection (IP) rating, which describes their degree of resistance to ingress of objects, dust, and water (IEC *Standard* 60529).

Pilot lights are replaceable incandescent or light-emitting diode (LED) lights that indicate the status or mode of operation of mechanical and electrical equipment. They are panel-mounted, and may be round or flat, of various colors, and powered using either AC or DC power. They are typically installed in an enclosure rated for the application under NEMA *Standard* 250, or with an appropriate IP rating.

Strobes use a high-intensity xenon flash tube to generate a high-intensity light that is visible in all directions. If this device is used in a safety application (e.g., refrigeration monitoring), in the United States, it must comply with UL *Standard* 1971 and the Americans with Disabilities Act (ADA), Title III; in Canada, with ULC *Standard* S526; elsewhere, it must meet requirements of British Standards Institution (BSI) *Standard* BS EN 54-23.

Horns provide an audible tone with a specified loudness rated in decibels (dB), and are mounted in a panel or junction box. The tone may be continuous, warbled, short beeps, or long beeps. The tone should be at least 10 dB above the ambient noise level in the area that the device is mounted. The operating voltage may be either DC or AC. When used in a life safety application, it must comply with NFPA *Standard* 72 or BSI *Standard* BS EN 54-3.

3. COMMUNICATION NETWORKS FOR BUILDING AUTOMATION SYSTEMS

A **building automation system (BAS)** is a centralized control and/or monitoring system for many or all building systems (e.g., HVAC, electrical, life safety, security). A BAS may link information from control systems actuated by different technologies.

Licensed for single user. © 2021 ASHRAE, Inc.

One important characteristic of a BAS is the ability to share information. Information is transferred between (1) controllers to coordinate their action, (2) controllers and building operator interfaces to monitor and command systems, and (3) controllers and other computers for off-line calculation. This information is typically shared over communication networks. A BAS nearly always involves at least one network; often, two or more networks are interconnected to form an **internetwork**.

3.1 COMMUNICATION PROTOCOLS

A communication protocol is a set of rules that define exchange of information between devices on a communication network. These rules define the content and format of messages to be exchanged, what information it contains, how it is routed/received, what error detection and recovery is used, and what response is given. They also describe the addressing and naming used to identify devices as well as the interaction between them, how to respond to new devices, what to do when devices fail, and when/how often a device is allowed to initiate or respond to a new message.

Layering allows portions of the technology to be used by a wide variety of applications, and thus lowers the cost because of economies of scale. For example, one of the most widely used computer communication standards is the Institute of Electrical and Electronics Engineers (IEEE) *Standard* 802.3 (Ethernet). Ethernet is a general-purpose mechanism for exchanging information across a local area network (LAN). Ethernet networks are used for many applications, including e-mail, file transfer, web browsing, and building control systems. However, two devices on the same Ethernet may be completely unable to communicate because Ethernet does not define the content of messages to be exchanged.

Open protocols for building automation systems facilitate communication among devices from different suppliers. Although there is no commonly accepted definition of *openness*, IEEE *Standard* 802.3 defines three classes of protocols:

- **Standard protocol.** Published and controlled by a standards body.
- **Public protocol.** Published but controlled by a private organization.
- **Private protocol.** Unpublished; use and specification controlled by a private organization. Examples include the proprietary communications used by many building automation devices.

Multivendor communication is possible with any of these three classes, but the challenges vary. Specifying a standard or widely used public protocol can improve the chances for a competitive bidding process and provide economic options for future expansions. However, specifying a common protocol does not ensure that the requirement for interoperability is met. It is also necessary to specify the desired interaction between devices.

3.2 OSI NETWORK MODEL

ISO *Standard* 7498-1 presents a seven-layer model of information exchange called the Open Systems Interconnection (OSI) Reference Model (Figure 19).

Most computer networks, especially open networks, are based on this reference model. The layers can be thought of as steps in the translation of a message from something with meaning at the application layer, to something measurable at the physical layer, and back to meaningful information at the application layer.

The full seven-layer model does not apply to every network, but it is still used to describe the aspects that fit. When describing DDC networks that use the same technology throughout the system, the seven-layer model is relatively unimportant. For systems that use various technologies at different points in the network, the model helps to describe where and how the pieces are bound together.

7 Application Layer	Window between applications and network.
6 Presentation Layer	Coordinates representation of information between different applications.
5 Session Layer	Synchronizes and structures exchange of data messages between specific users.
4 Transport Layer	Converts data messages into packets for transmission, and converts received packets into messages. Responsible for data message error recognition and recovery, and ensures reliable delivery of messages.
3 Network Layer	Addressing and routing packets independent of media and topology.
2 Data Link Layer	Responsible for point-to-point reliability. Media access. Representation of bits and bytes as physical signals. Organizes bits into data packets.
1 Physical Layer	Electrical characteristics of devices and conductors.

Fig. 19 OSI Reference Model

3.3 NETWORK STRUCTURE

BAS Three-Tier Network Architecture

Often, a single BAS applies different network technologies at different points in the system. For example, a relatively low-speed, inexpensive network with relatively primitive functions may link a group of room controllers to a supervisory controller, while a faster, more sophisticated network links the supervisory controller to its peers and to one or more operator workstations. Figure 20 demonstrates the representation and interaction of a multitier BAS system architecture as described in ASHRAE *Guideline* 13-2015. The architecture model has three tiers. Tier 1 is the enterprise-level information technology (IT) network and provides access to user interfaces, dashboards, kiosks, and application interfaces. Tier 2 is the building network infrastructure and includes the building control network connectivity to the building IT network. Tier 3 is the control network and the associated controllers, equipment, sensors, and actuators.

The opposite extreme is completely **flat network architecture**, which links all devices through the same network. A flat architecture is more viable in small systems than in large ones, because economic constraints typically dictate that low-cost (and therefore low-speed) networks be used to connect field-level controllers. Because of their performance limitations, these networks do not scale well to large numbers of devices. As the cost of electronics for communication drops, flatter networks become more feasible.

Network structure can affect

- Opportunities for expansion of a BAS.
- Reliability and failure modes. It may be appropriate to separate sections of a network to isolate failures.
- How devices load the information-carrying capacity of the network. It can isolate one busy branch from the rest of the system, or isolate branches from the high-speed backbone.
- How and where information is displayed to operating personnel; web servers accessible through the Internet make BAS information available to anyone, anywhere, who has a standard web browser and access rights to view the server pages.
- System cost, because it determines the mix of low- and high-speed devices.
- System data security and access control.

Licensed for single user. © 2021 ASHRAE, Inc.

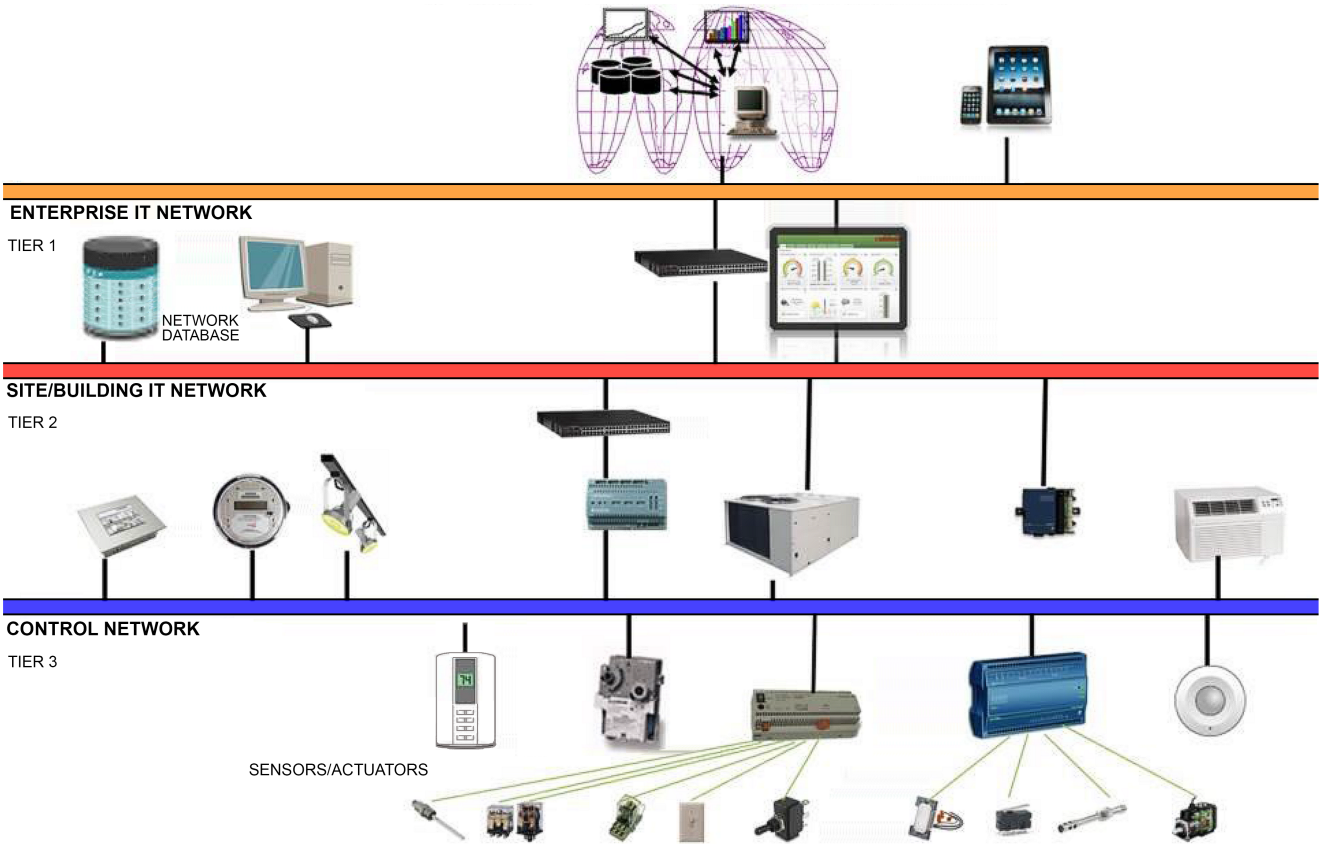

Fig. 20 Hierarchical Network for Three-Tier System Architecture

The relative merits of one structure versus another depend on the communication functions required, hardware and software available for the task, and cost. For a given job, there is probably more than one suitable structure. Product capabilities change quickly. Engineers who choose to specify network structure must be aware of new technologies to take advantage of the most cost-effective solutions.

Connections Between BAS Networks and Other Computer Networks

Some BAS networks use other networks to connect segments of the BAS. This occurs

- Within a building, using the information technology network
- Between buildings, using an intranet or the Internet
- Between buildings, using telephone lines, wireless links, or fiber optics

In each case, the link between BAS segments must be considered part of the BAS network when evaluating function, security, and performance. The link also raises new issues. The connecting segment is likely to be outside the control of the owner of the BAS, which could affect availability of service. Traffic and bandwidth issues may have to be addressed with the link administrator.

Using a dial-up connection to interact with a remote building or to serve a remote operator requires consideration of which segment may dial the other, what circumstances trigger the call, and security implications. Handling interbuilding communication through intranet or Internet connections, with the operator interface provided by a web browser communicating with a web server, has largely replaced dial-up connections.

Transmission Media

The transmission medium is the foundation of the network. It is usually, but not always, cable. The cable may be plenum rated or non-plenum rated, depending on the installation application. Where physical cable connection is not possible or practical, devices may transfer information using wireless technologies, such as radio waves or infrared light.

RS-485 is the data link layer standard most commonly used in BAS for communications inside a building. It works over a single shielded twisted pair, 0.51 to 1.02 mm diameter, and can reach distances of up to 500 m between repeaters and up to 120 devices per segment. It has no polarity (i.e., no positive and negative wires), which reduces wiring errors, and in most cases is optically isolated at the controllers, allowing for different power sources without risk of short circuits.

ANSI/TIA/EIA *Standard* 568-B.1 provides IT cabling specifications for commercial buildings. This cabling is used for computers and telephone networks and can also be used for low-level BAS, access, security, or fire detection systems, but close work between the BAS and IT design and execution teams is required. The potential for third-party devices halting all network traffic discourages its use for control and security applications, as does the location of outlets prescribed in the standard (in occupied spaces instead of plenums and mechanical rooms where the controllers are). Also, IT network administrators are sometimes reluctant to allow connection of unfamiliar devices they cannot configure.

Cable length. Maximum length varies with cable type, transmission speed, and protocol.

100 Ω Balanced Twisted-Pair Communications Outlet/Connector. Each four-pair cable terminates on an eight-position mod-

Licensed for single user. © 2021 ASHRAE, Inc.

ular jack, and all unshielded twisted-pair (UTP) and screened twisted-pair (ScTP) telecommunications outlets must meet the requirements of IEC *Standard* 60603-7, as well as ANSI/TIA/EIA *Standard* 568-B.2 and the terminal marking and mounting requirements of ANSI/TIA/EIA *Standard* 570-B.

Twisted-Pair Copper Cable. A twisted-pair cable consists of multiple twisted pairs (typically 0.51 mm diameter) of wire covered by an overall sheath or jacket. Varying the number of twists for each pair relative to the other pairs in the cable can greatly reduce crosstalk (interference between signals on different pairs).

Screened twisted-pair (ScTP) cable is similar in construction to UTP data cabling, except that ScTP has a foil shield between the conductors and outer jacket, as well as a drain wire used to minimize interference-related problems. ScTP cable is preferred over UTP cable in environments where high immunity and/or low emissions are critical. It also allows less crosstalk than UTP. However, ScTP requires more labor-intensive installation, and any break or improper grounding of the shield reduces its overall effectiveness.

Category 3 cable connects hardware and patch cords that are rated to a maximum frequency of 16 MHz. This cable is rated up to 16 megabits per second. This category is usually the lowest level of cable installed and is used mainly for voice and low-speed networks.

Category 5 cable connects hardware and patch cords that are rated to a maximum frequency of 100 MHz. The actual data transmission rate varies with the compression scheme used. Category 5 was defined in ANSI/TIA/EIA *Standard* 568-A, but is no longer recognized in the new ANSI/TIA/EIA *Standard* 568-B.1.

Category 5e cable connects hardware and patch cords that are rated to a maximum frequency of 100 MHz. The actual data transmission rate varies with the compression or encoding scheme used. Category 5e, the lowest category recommended for data installations, is defined by ANSI/TIA/EIA *Standards* 568-B.1 and B.2. This cable is rated up to 100 megabits per second.

Category 6 cable connects hardware and patch cords that are rated to a maximum frequency of 250 MHz, though the actual data transmission rate varies with the compression scheme used. UTP or STP cable is currently the most common medium. This cable is rated up to 1 gigabit per second.

Category 6e cable connects hardware and patch cords that are rated to a maximum frequency of 250 MHz, though actual data transmission rate varies with the compression scheme used. With all Category 6 systems, an eight-position jack is mandatory in the work area.

Category 7 cable connects hardware and patch cords that are rated to a maximum frequency of 600 MHz, though actual data transmission rate varies with the compression scheme used. This category is still in development and uses a braided shield surrounding all four foil-shielded pairs to reduce noise and interference. Depending on future technological developments, the current RJ-45 connector will not be used in Category 7.

Fiber-Optic Cable. Fiber-optic cable uses glass or plastic fibers to transfer data in the form of light pulses, which are typically generated by either a laser or an LED. Fiber-optic cable systems are classified as either single-mode fiber or multimode fiber systems. Table 1 compares their characteristics.

Light in a fiber-optic system loses less energy than electrical signals traveling through copper and has no capacitance. This translates into greater transmission distances and dramatically higher data transfer rates, which impose no limits on a BAS. Fiber optics also have exceptional noise immunity. However, the necessary conversions between light-based signaling and electricity-based computing make fiber optics more expensive per device, which sometimes offsets its advantages.

Structured Cabling. ANSI/TIA/EIA *Standard* 568 allows cable planning and installation to begin before the network engineering is finalized. It supports both voice and data. The standard was written for the telecommunications industry, but cabling is gaining recognition as building infrastructure, and the standard is being applied to BAS networks as well.

Table 1 Comparison of Fiber Optic Technology

	Multimode Fiber	Single-Mode Fiber
Light source	LED	Laser
Cable designation (core/cladding diameter)	62.6/125	8.3/125
Transmission distance	2000 m	30 000 m
Data rate	>10 gigabit/s and increasing	Even higher
Relative cost	Less per connection, more per data rate	More per connection, less per data rate

ANSI/TIA/EIA *Standard* 568-B specifies **star topology** (each device individually cabled to a hub) because connectivity is more robust and management is simpler than for busses and rings. If the wires in a leg are shorted, only that leg fails, making fault isolation easier; with a bus, all drops would fail.

The basic structure specified is a **backbone**, which typically runs from floor to floor in a building and possibly between buildings. **Horizontal cabling** runs between the distribution frames on each floor and the information outlets in the work areas.

Wireless Networks. The rapid maturity of everyday wireless technologies, now widely used for mobile phones, Internet access, and even barcode replacement, has tremendously increased the ability to collect information from the physical world. Wireless technologies offer significant opportunities in sensors and controls for building operation, especially in reducing the cost of installing data acquisition and control devices. Installation costs typically represent 20 to 80% of the total cost of a sensor and control point in any HVAC system, so reducing or eliminating the cost of installation can have a dramatic effect on the overall installed system cost. Low-cost wireless sensors and control systems also make it economical to use more sensors, thereby establishing highly energy-efficient building operations and demand responsiveness that enhance the electric grid reliability.

Wireless sensors and control networks consist of sensor and control devices that are connected to a network using radio-frequency (RF) or optical (infrared) signals. Devices can communicate bidirectionally (i.e., transmitting and receiving) or one way (transmitting only). Most RF products transmit in the industrial, scientific, or medical frequency bands, which are set aside by the Federal Communication Commission (FCC) for use without an FCC license. Wireless sensor networks have different requirements than computer networks and, thus, different network topologies, and separate communication protocols have evolved for them. The simplest is the **point-to-point topology**, in which two nodes communicate directly with each other. The **point-to-multipoint** or **star topology** is an extension of the point-to-point configuration in which many nodes communicate with a central receiving or gateway node. In either topology, sensor nodes might have pure transmitters, which provide one-way communication only, or transceivers, which allow two-way communication and verification of the receipt of messages. Gateways provide a means to convert and pass data between protocols (e.g., from a wireless sensor network protocol to the wired Ethernet protocol).

The communication range of the point-to-point and star topologies is limited by the maximum communication range between the sensor node (from which the measured data originates) and the receiver node. This range can be extended by using repeaters, which receive transmissions from sensor nodes and then retransmit them, usually at higher power than the original transmissions. In the **mesh network topology**, each sensor node includes a transceiver that can communicate directly with any other node within its communication range. These networks connect many devices to many other

Licensed for single user. © 2021 ASHRAE, Inc.

devices, thus forming a mesh of nodes in which signals are transmitted between distant points via multiple hops. This approach decreases the distance over which each node must communicate and reduces each node's power use substantially, making them more compatible with onboard power sources such as batteries (Capehardt 2005).

3.4 SPECIFYING BUILDING AUTOMATION SYSTEM NETWORKS

Specifying a building automation system includes specifying a platform comprising the following components: field device (e.g., sensors, actuators), controllers (e.g., equipment and/or supervisory), and information management and network communication (e.g., security, diagnostics, maintenance). Many technologies can deliver many performance levels at many different prices. Building automation system design requires assessing the owner's risk tolerance against the proposed project budget. In some cases, new equipment must interface with existing devices, which may limit networking options. ASHRAE *Guideline* 13-2015 provides detailed information on how to specify a building automation system.

Communication Tasks

Determining network performance requirements means identifying and quantifying the communication functions required. Ehrlich and Pittel (1999) identified the following five basic communication tasks necessary to establish network requirements.

Data Exchange. What data passes between which devices? What control and optimization data passes between controllers? What update rates are required? What data does an operator need to reach? How much delay is acceptable in retrieving values? What update rates are required on "live" data displays? (Within one system, answers may vary according to data use.) Which set points and control parameters do operators need to adjust over the network?

Alarms and Events. Where do alarms originate? Where are they logged and displayed? How much delay is acceptable? Where are they acknowledged? What information must be delivered along with the alarm? (Depending on system design, alarm messages may be passed over the network along with the alarms.) Where are alarm summary reports required? How and where do operators need to adjust alarm limits, etc.?

Schedules. For HVAC equipment that runs on schedules, where can the schedules be read? Where can they be modified?

Trends. Where does trend data originate? Where is it stored? How much will be transmitted? Where is it displayed and processed? Which user interfaces can set and modify trend collection parameters?

Network Management. What network diagnostic and maintenance functions are required at which user interfaces? Data access and security functions may be handled as network management functions.

Bushby et al. (1999) refer to the same five communication tasks as **interoperability areas** and list many more specific considerations in each area. ASHRAE *Guideline* 13 also provides more detailed information that is helpful.

3.5 APPROACHES TO INTEROPERABILITY

Many approaches to interoperability have been proposed and applied, each with varying degrees of success under various circumstances. The field changes quickly as product lines emerge and standards develop and gain acceptance. The building automation world continues to evaluate options project by project.

Typically, an interoperable system uses one of two approaches: standard protocols or special-purpose gateways. With a standard, the supplier is responsible for compliance with the standard; the system specifier or integrator is responsible for interoperation. With a gateway, the supplier takes responsibility for interoperation. Where the job requires interoperation with existing equipment, gateways may be the only solution available. Bushby (1998) addressed this issue and some of the limitations associated with gateways. To date, interoperability by any method requires solid field engineering and capable system integration; the issues extend well beyond the selection of a communication protocol.

Table 2 Some Standard Communication Protocols Applicable to BAS

Protocol	Definition
BACnet®	ANSI/ASHRAE *Standard* 135-2012, EN/ISO *Standard* 16484-5:2013
LonTalk	ANSI/CEA *Standard* 709.1
PROFIBUS FMS	EN 50170:2000 Volume 2
Konnex	EN 50090
MODBUS	Modbus Application Protocol Specification V1.1
ZigBee®	ZigBee® Commercial Building Automation Profile Specification

Standard Protocols

Table 2 lists some applicable standard protocols that have been used in BAS. Their different characteristics make some more suited to particular tasks than others. PROFIBUS (www.profibus.com) and MODBUS (www.modbus.org) were designed for low-cost industrial process control and automated manufacturing applications, but they have been applied to BAS. LonTalk defines a LAN technology but not messages that are to be exchanged for BAS applications. BACnet® or implementers' agreements, such as those made by members of LonMark International, are necessary to achieve interoperability with LonTalk devices. Konnex evolved from the European Installation Bus (EIB) and several other European protocols developed for residential applications, including multifamily housing. ZigBee® is an open communications standard for wireless devices developed by the ZigBee Alliance. Annex O of the BACnet standard (ANSI/ASHRAE *Standard* 135-2013) specifies using BACnet messaging with services described in the ZigBee specification. Martocci (2008) describes how a wireless ZigBee network can be integrated into a BACnet network.

BACnet is the only standard protocol developed specifically for commercial BAS applications. BACnet has been adopted as a national standard in the United States, Korea, and Japan, as a European standard, and as a world standard (EN/ISO *Standard* 16484-5). BACnet was designed to be used with non-BACnet networks. Principles of mapping are documented in Annex H of ANSI/ASHRAE *Standard* 135-2012.

Gateways and Interfaces

Rather than conforming to a published standard, a supplier can design a specific device to exchange data with another specific device. This typically requires cooperation between two manufacturers. In some cases, it can be simpler and more cost-effective than for both manufacturers to conform to an agreed-upon standard. The device can be either custom-designed or off the shelf. In either case, the communication tasks must be carefully specified to ensure that the gateway performs as needed.

Choosing a system that supports a variety of gateways may be a way to maintain a flexible position as products and standards continue to develop.

4. SPECIFYING BUILDING AUTOMATION SYSTEMS

Successful building automation system (BAS) installation depends in part on a clear description (specification) of what is

Licensed for single user. © 2021 ASHRAE, Inc.

required to meet the customer's needs. The specification should include descriptions of the products desired, or of the performance and features expected. Needed points or data objects should be listed. A control schematic shows the layout of each system to be controlled, including instrumentation and input/output objects and any hard-wired interlocks.

Writing a descriptive network specification requires knowledge of the details of network technology. To succeed with any specification, the designer must articulate the end user's needs. Typically, performance-based specification is the best value for the customer (Ehrlich and Pittel 1999).

The sequences of operation describe how the system should function and are the designer's primary method of communication to the control system programmer. A sequence should be written for each system to be controlled. In writing a sequence, be sure to describe all operational modes and ensure that all input/output (I/O) devices needed to implement the sequence are shown on the object list and drawings.

Annex A of ASHRAE *Guideline* 13-2015 shows a sample specification outline for a building automaton system. Information on specifying building automaton systems is in *MasterFormat* (CSI 2004): Division 23, Section 23 09 00, or in Division 25. Additional information on specifying BAS controls and sample sequences of control for air-handling systems can be found in ASHRAE *Guideline* 13.

5. COMMISSIONING

Commissioning controls can refer either to the proper configuration and tuning of a controller or, more broadly, a standard process of quality assurance to ensure that owner's requirements are met, design intent is achieved, and staff is well prepared for operation and maintenance. Because individual pieces of equipment are often tied together into larger systems, and sequences of operation on these systems (affecting safety, indoor air quality, comfort, and energy efficiency) are implemented through controls configuration and programming, building performance is highly dependent on the quality of controls design and implementation.

A successful control system requires proper start-up, testing, and documentation, not merely adjustment of a few parameters (set points and throttling ranges) and a few quick checks.

Because of the impact on building performance, controls have become a significant focus of the building commissioning process. The typical BAS system should be commissioned directly using an experienced, unbiased third party; this is an effective way to test and document HVAC system performance.

The commissioning process requires coordination between the owner, designers, and contractors, and is most effective when it begins before the start of design and continues for the life of the building. Issues are tracked and results are documented throughout the process. Design and construction specifications should include specific commissioning procedures. Review submittals for conformance to design. Check each control device to ensure that it is installed and connected according to approved drawings. Each connection should be verified, and all safeties and sequences tested. Performance assessment should continue after occupancy, especially for large equipment, to identify and address degradation over time. Chapter 44 of the 2019 *ASHRAE Handbook—HVAC Applications* and ASHRAE *Guideline* 1 explain more about commissioning.

Package controls of high-cost equipment (e.g., chillers, preassembled plants) or that may pose safety risks (e.g., boilers) should always be commissioned by factory-authorized service providers. Because factory-supplied equipment and controls are usually integrated into larger systems, some on-site commissioning is still appropriate.

5.1 TUNING

Systematic tuning of controllers improves performance of all controls and is particularly important for digital control. First, the controlled process should be controlled manually between various set points to evaluate the following questions:

- Is the process noisy (rapid fluctuations in controlled variable)?
- Is there appreciable hysteresis (backlash) in the actuator?
- How easy (or difficult) is it to maintain and change set point?
- In which operating region is the process most sensitive (highest gain)?

If the process cannot be controlled manually, the reason should be identified and corrected before the controller is tuned.

Tuning optimizes control parameters that determine steady-state and transient characteristics of the control system. HVAC processes are nonlinear, and characteristics change seasonally. Controllers tuned under one operating condition may become unstable as conditions change.

A well-tuned controller (1) minimizes steady-state error for set point, (2) responds with appropriate timing to disturbances, and (3) remains stable under all operating conditions. Tuning proportional controllers is a compromise between minimizing steady-state error and maintaining margins of stability. Proportional plus integral (PI) control minimizes this compromise because the integral action reduces steady-state error, and the proportional term determines the controller's response to disturbances.

As performance requirements have become more stringent, sequences of operation have become increasingly complex, and the task of tuning has also become more challenging. Some manufacturers now provide self-tuning routines to avoid the need for manual adjustment and help maintain performance with changing conditions.

Tuning Proportional, PI, and PID Controllers

Popular methods of determining proportional, PI, and PID controller tuning parameters include closed- and open-loop process identification methods and trial-and-error methods. For each method, carefully consider the resulting timing of system responses to avoid compromising safety or reducing the expected life of equipment. Two of the most widely used techniques for tuning these controllers are ultimate oscillation and first-order-plus-dead-time. There are many optimization calculations for these two techniques. The Ziegler-Nichols, which is given here, is well established.

Ultimate Oscillation (Closed-Loop) Method. The closed-loop method increases controller gain in proportional-only mode until the equipment continuously cycles after a set-point change (Figure 21, where $K_p = 40$). Proportional and integral terms are then computed from the cycle's period of oscillation and the K_p value that caused cycling. The ultimate oscillation method is as follows:

1. Adjust control parameters so that all are essentially off. This corresponds to a proportion band (gain) at its maximum (minimum), the integral time (repeats per minute) or integral gain to maximum (minimum), and derivative to its minimum.
2. Adjust manual output of the controller to give a measurement as close to midscale as possible.
3. Put controller in automatic.
4. Gradually increase proportional feedback (this corresponds to reducing the proportional band or increasing the proportional gain) until observed oscillations neither grow nor diminish in amplitude. If response saturates at either extreme, start over at Step 2 to obtain a stable response. If no oscillations are observed, change the set point and try again.

Licensed for single user. © 2021 ASHRAE, Inc.

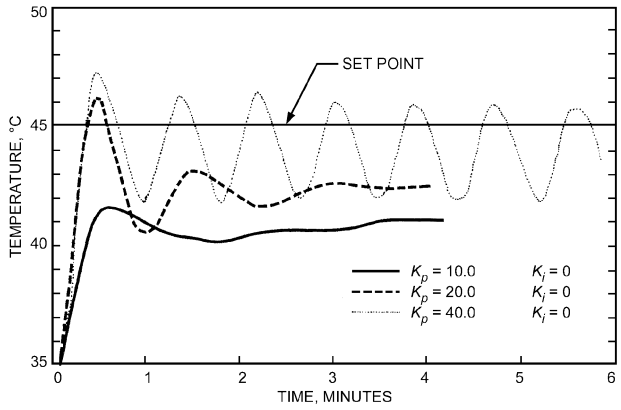

Fig. 21 Response of Discharge Air Temperature to Step Change in Set Points at Various Proportional Constants with No Integral Action

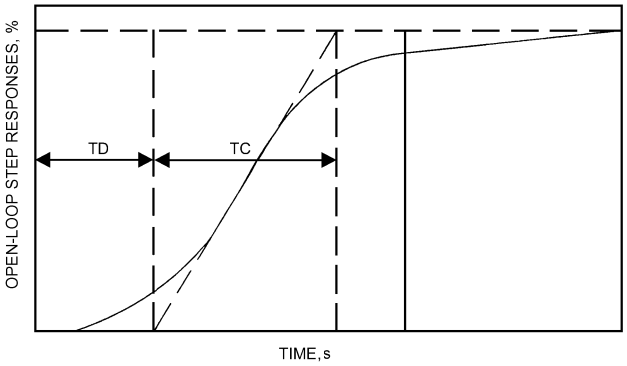

Fig. 22 Open-Loop Step Response Versus Time

5. Record the proportional band as PB_u and the period of oscillations as T_u.
6. Use the recorded proportional band and oscillation period to calculate controller settings as follows:

Proportional only:

$$PB = 1.8(PB_u) \quad \text{percent} \tag{4}$$

Proportional plus integral (PI):

$$PB = 2.22(PB_u) \quad \text{percent} \tag{5}$$

$$T_i = 0.83T_u \quad \text{minute per repeat} \tag{6}$$

Proportional plus integral plus derivative (PID):

$$PB = 1.67(PB_u) \quad \text{percent} \tag{7}$$

$$T_i = 0.50T_u \quad \text{minute per repeat} \tag{8}$$

$$T_d = 0.125T_u \quad \text{minute} \tag{9}$$

First-Order-plus-Dead-Time (Open-Loop) Method. The open-loop method introduces a step change in input into the opened control loop. A graphical technique is used to estimate the process transfer function parameters. Proportional and integral terms are calculated from the estimated process parameters using a series of equations.

The value of the process variable must be recorded over time, and the dead time and time constant must be determined from it. This can be accomplished graphically, as seen in Figure 22. The first-order-plus-dead-time method is as follows:

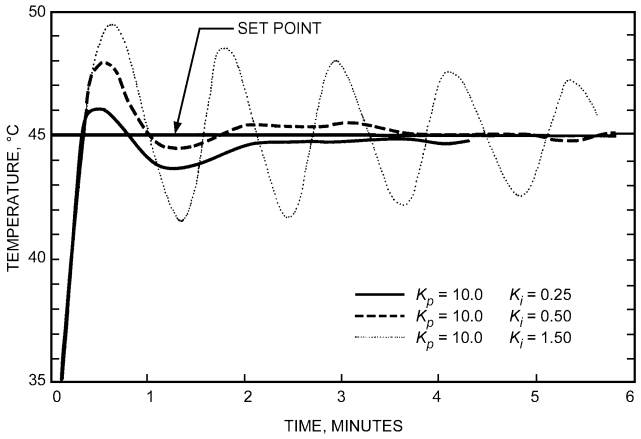

Fig. 23 Response of Discharge Air Temperature to Step Change in Set Points at Various Integral Constants with Fixed Proportional Constant

1. Adjust controller manual output to give a midscale measurement.
2. Arrange to record the process variable over time.
3. Move the manual output of the controller by 10% as rapidly as possible to approximate a step change.
4. Record the value of the process variable over time until it reaches a new steady-state value.
5. Determine dead time and time constant.
6. Use dead time (TD) and time constant (TC) values to calculate PID values as follows:

$$\text{Gain} = \frac{\%\text{ change in controlled variable}}{\%\text{ change in control signal}} \tag{10}$$

Proportional only:

$$PB = \text{Gain}/(TC/TD) \tag{11}$$

Proportional plus integral (PI):

$$PB = 0.9(\text{Gain})/(TC/TD) \tag{12}$$

$$T_i = 3.33(TD) \tag{13}$$

Proportional-integral-derivative (PID):

$$PB = 1.2(\text{Gain})/(TC/TD) \tag{14}$$

$$T_i = 2(TD) \tag{15}$$

$$T_d = 0.5(TD) \tag{16}$$

Trial and Error. This method involves adjusting the gain of the proportion-only controller until the desired response to a set point is observed. Conservative tuning dictates that this response should have a small initial overshoot and quickly damp to steady-state conditions. Set-point changes should be made in the range where controller saturation, or output limit, is avoided. The integral term is then increased until changes in set point produce the same dynamic response as the controller under proportional control, but with the response now centered about the set point (Figure 23).

Tuning Digital Controllers

In tuning digital controllers, additional parameters may need to be specified. The digital controller sampling interval is critical because it can introduce harmonic distortion if not selected properly. This sampling interval is usually set at the factory and may not be adjustable. A controller sampling interval of about one-tenth of the controlled-process time constant usually provides adequate control. Many digital control algorithms include an error dead band to eliminate unnecessary control actions when the process is near set

Licensed for single user. © 2021 ASHRAE, Inc.

point. Hysteresis compensation is possible with digital controllers, but it must be carefully applied because overcompensation can cause continuous cycling of the control loop.

Computer Modeling of Control Systems

Each component of a control system can be represented by a transfer function, which is an idealized mathematical representation of the relationship between the input and output variables of the component. The transfer function must be sufficiently detailed to cover both the dynamic and static characteristics of the device. The dynamics are represented in the time domain by a differential equation. In environmental control, the transfer function of many of the components can be adequately described by a first-order differential equation, implying that the dynamic behavior is dominated by a single capacitance factor. For a solution, the differential equation is converted to its Laplace or *z*-transform.

For more information on computer modeling programs, see Chapter 40 of the 2015 *ASHRAE Handbook—HVAC Applications*.

SOUND AND VIBRATION

Acoustical Design Objective 8.1
Characteristics of Sound 8.1
Measuring Sound 8.4
Determining Sound Power 8.7
Converting from Sound Power to Sound Pressure 8.8
Sound Transmission Paths 8.9
Typical Sources of Sound 8.10
Controlling Sound 8.11
System Effects 8.13
Human Response to Sound 8.14
Sound Rating Systems and Acoustical Design Goals 8.15
Fundamentals of Vibration 8.17
Vibration Measurement Basics 8.19
Symbols 8.19

IF FUNDAMENTAL principles of sound and vibration control are applied in the design, installation, and use of HVAC&R systems, suitable levels of noise and vibration can be achieved with a high probability of user acceptance. This chapter introduces these fundamental principles, including characteristics of sound, basic definitions and terminology, human response to sound, acoustic design goals, and vibration isolation fundamentals. Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* and the references at the end of this chapter contain technical discussions, tables, and design examples helpful to HVAC designers.

1. ACOUSTICAL DESIGN OBJECTIVE

A primary objective in the design of HVAC systems and equipment is to evaluate noise and vibration to ensure that the acoustical environment in a given space is acceptable for various occupant activities. Sound and vibration are created by a **source**, are transmitted along one or more **paths**, and reach a **receiver**. Treatments and modifications can be applied to any or all of these elements to reduce unwanted noise and vibration, although it is usually most effective and least expensive to reduce noise at the source.

2. CHARACTERISTICS OF SOUND

Sound is a propagating disturbance in a fluid (gas or liquid) or in a solid. In fluid media, the disturbance travels as a longitudinal compression wave. Sound in air is called *airborne sound* or just *sound*. It is generated by a vibrating surface or turbulent fluid stream. In solids, sound can travel as bending, compressional, torsional, shear, or other waves, which, in turn, are sources of airborne sound. Sound in solids is generally called *structureborne sound*. In HVAC system design, both airborne and structureborne sound propagation are important.

Levels

The magnitude of sound and vibration physical properties are almost always expressed in *levels*. As shown in the following equations, the level L is based on the common (base 10) logarithm of a ratio of the magnitude of a physical property of power, intensity, or energy to a reference magnitude of the same type of property:

$$L = 10 \log\left(\frac{A}{A_{ref}}\right) \quad (1)$$

where A is the magnitude of the physical property of interest and A_{ref} is the reference value. Note that the ratio is dimensionless. In this equation, a factor of 10 is included to convert bels to decibels (dB).

The preparation of this chapter is assigned to TC 2.6, Sound and Vibration.

Sound Pressure and Sound Pressure Level

Sound waves in air are variations in pressure above and below atmospheric pressure. **Sound pressure** is measured in pascals (Pa). The human ear responds across a broad range of sound pressures; the threshold of hearing to the threshold of pain covers a range of approximately 10^{14}:1. Table 1 gives approximate values of sound pressure by various sources at specified distances from the source.

The range of sound pressure in Table 1 is so large that it is more convenient to use a scale proportional to the logarithm of this quantity. Therefore, the **decibel** (dB) scale is the preferred method of presenting quantities in acoustics, not only because it collapses a large range of pressures to a more manageable range, but also because its levels correlate better with human responses to the magnitude of sound than do sound pressures. Equation (1) describes levels of power, intensity, and energy, which are proportional to the square of other physical properties, such as sound pressure and vibration acceleration. Thus, the **sound pressure level** L_p corresponding to a sound pressure is given by

$$L_p = 10 \log\left(\frac{p}{p_{ref}}\right)^2 = 20 \log\left(\frac{p}{p_{ref}}\right) \quad (2)$$

where p is the root mean square (RMS) value of acoustic pressure in pascals. The root mean square is the square root of the time average of the square of the acoustic pressure ratio. The ratio p/p_{ref} is squared to give quantities proportional to intensity or energy. A

Table 1 Typical Sound Pressures and Sound Pressure Levels

Source	Sound Pressure, Pa	Sound Pressure Level, dB re 20 μPa	Subjective Reaction
Military jet takeoff at 30 m	200	140	Extreme danger
Artillery fire at 3 m	63.2	130	
Passenger jet takeoff at 15 m	20	120	Threshold of pain
Loud rock band	6.3	110	Threshold of discomfort
Automobile horn at 3 m	2	100	
Unmuffled large diesel engine at 40 m	0.6	90	Very loud
Accelerating diesel truck at 15 m	0.2	80	
Freight train at 30 m	0.06	70	Loud
Conversational speech at 1 m	0.02	60	
Window air conditioner at 3 m	0.006	50	Moderate
Quiet residential area	0.002	40	Quiet
Whispered conversation at 2 m	0.0006	30	
Buzzing insect at 1 m	0.0002	20	Perceptible
Threshold of good hearing	0.00006	10	Faint
Threshold of excellent youthful hearing	0.00002	0	Threshold of hearing

reference quantity is needed so the term in parentheses is nondimensional. For sound pressure levels in air, the reference pressure p_{ref} is 20 μPa, which corresponds to the approximate threshold of hearing for a young person with good hearing exposed to a pure tone with a frequency of 1000 Hz.

The decibel scale is used for many different descriptors relating to sound: source strength, sound level at a specified location, and attenuation along propagation paths; each has a different reference quantity. For this reason, it is important to be aware of the context in which the term *decibel* or *level* is used. For most acoustical quantities, there is an internationally accepted reference value. A reference quantity is always implied even if it does not appear.

Sound pressure level is relatively easy to measure and thus is used by most noise codes and criteria. (The human ear and microphones are pressure sensitive.) Sound pressure levels for the corresponding sound pressures are also given in Table 1.

Frequency

Frequency is the number of oscillations (or cycles) completed per second by a vibrating object. The international unit for frequency is hertz (Hz) with dimension s^{-1}. When the motion of vibrating air particles is simple harmonic, the sound is said to be a **pure tone** and the sound pressure p as a function of time and frequency can be described by

$$p(t, f) = p_0 \sin(2\pi f t) \quad (3)$$

where f is frequency in hertz, p_0 is the maximum amplitude of oscillating (or acoustic) pressure, and t is time in seconds.

The **audible frequency range** for humans with unimpaired hearing extends from about 20 Hz to 20 kHz. In some cases, infrasound (<20 Hz) or ultrasound (>20 kHz) are important, but methods and instrumentation for these frequency regions are specialized and are not considered here.

Speed

The speed of a longitudinal wave in a fluid is a function of the fluid's density and bulk modulus of elasticity. In air, at room temperature, the speed of sound is about 340 m/s; in water, about 1500 m/s. In solids, there are several different types of waves, each with a different speed. The speeds of **compressional**, **torsional**, and **shear waves** do not vary with frequency, and are often greater than the speed of sound in air. However, these types of waves are not the primary source of radiated noise because resultant displacements at the surface are small compared to the internal displacements. **Bending waves**, however, are significant sources of radiation, and their speed changes with frequency. At lower frequencies, bending waves are slower than sound in air, but can exceed this value at higher frequencies (e.g., above approximately 1000 Hz).

Wavelength

The wavelength of sound in a medium is the distance between successive maxima or minima of a simple harmonic disturbance propagating in that medium at a single instant in time. Wavelength, speed, and frequency are related by

$$\lambda = c/f \quad (4)$$

where

λ = wavelength, m
c = speed of sound, m/s
f = frequency, Hz

Sound Power and Sound Power Level

The **sound power** of a source is its rate of emission of acoustical energy and is expressed in watts. Sound power depends on operating conditions but not distance of observation location from the source or surrounding environment. Approximate sound power outputs for common sources are shown in Table 2 with corresponding sound power levels. For **sound power level L_w**, the power reference is 10^{-12} W or 1 picowatt. The definition of sound power level is therefore

$$L_w = 10 \log(w/10^{-12}) \quad (5)$$

where w is the sound power emitted by the source in watts. (Sound power emitted by a source is not the same as the power consumed by the source. Only a small fraction of the consumed power is converted into sound. For example, a loudspeaker rated at 100 W may be only 1 to 5% efficient, generating only 1 to 5 W of sound power.) Note that the sound power level is 10 times the logarithm of the ratio of the power to the reference power, and the sound pressure is 20 times the logarithm of the ratio of the pressure to the reference pressure.

Table 2 Examples of Sound Power Outputs and Sound Power Levels

Source	Sound Power, W	Sound Power Level, dB re 10^{-12} W
Large rocket launch (e.g., space shuttle)	10^8	200
Jet aircraft at takeoff	10^4	160
Large pipe organ	10	130
Small aircraft engine	1	120
Large HVAC fan	0.1	110
Heavy truck at highway speed	0.01	100
Voice, shouting	0.001	90
Garbage disposal unit	10^{-4}	80
Voice, conversation level	10^{-5}	70
Electronic equipment ventilation fan	10^{-6}	60
Office air diffuser	10^{-7}	50
Small electric clock	10^{-8}	40
Voice, soft whisper	10^{-9}	30
Rustling leaves	10^{-10}	20
Human breath	10^{-11}	10

Most mechanical equipment is rated in terms of sound power levels so that comparisons can be made using a common reference independent of distance and acoustical conditions in the room. AHRI *Standard* 370-2011 is a common source for rating large air-cooled outdoor equipment. AMCA *Publication* 303-79 provides guidelines for using sound power level ratings. Also, AMCA *Standards* 301-90 and 311-05 provide methods for developing fan sound ratings from laboratory test data. Note, however, some HVAC equipment has sound data available only in terms of sound pressure levels; for example, AHRI *Standard* 575-2008 is used for water-cooled chiller sound rating for indoor applications. In such cases, special care must be taken in predicting the sound pressure level in a specific room (e.g., manufacturer's sound pressure data may be obtained in large spaces nearly free of sound reflection, whereas an HVAC equipment room can often be small and very reverberant).

Sound Intensity and Sound Intensity Level

The **sound intensity** I at a point in a specified direction is the rate of flow of sound energy (i.e., power) through unit area at that point. The unit area is perpendicular to the specified direction, and the units of intensity are watts per square metre. **Sound intensity level L_I** is expressed in dB with a reference quantity of 10^{-12} W/m^2; thus,

$$L_I = 10 \log(I/10^{-12}) \quad (6)$$

The instantaneous intensity I is the product of the pressure and velocity of air motion (e.g., particle velocity), as shown here:

$$I = pv \quad (7)$$

Licensed for single user. © 2021 ASHRAE, Inc.

Both pressure and particle velocity are oscillating, with a magnitude and time variation. Usually, the time-averaged intensity I_{ave} (i.e., the net power flow through a surface area, often simply called "the intensity") is of interest.

Taking the time average of Equation (7) over one period yields

$$I_{ave} = \text{Real}\{pv\} \tag{8}$$

where Real is the real part of the complex (with amplitude and phase) quantity. At locations far from the source and reflecting surfaces,

$$I_{ave} \approx p^2/\rho_0 c \tag{9}$$

where p is the RMS sound pressure, ρ_0 is the density of air (1.2 kg/m^3), and c is the acoustic phase speed in air (335 m/s). Equation (9) implies that the relationship between sound intensity and sound pressure varies with air temperature and density. Conveniently, the sound intensity level differs from the sound pressure level by less than 0.5 dB for temperature and densities normally experienced in HVAC environments. Therefore, sound pressure level is a good measure of the intensity level at locations far from sources and reflecting surfaces.

Note that all equations in this chapter that relate sound power level to sound pressure level are based on the assumption that sound pressure level is equal to sound intensity level.

Combining Sound Levels

To estimate the levels from multiple sources from the levels from each source, the intensities (not the levels) must be added. Thus, the levels must first be converted to find intensities, the intensities summed, and then converted to a level again, so the combination of multiple levels L_1, L_2, etc., produces a level L_{sum} given by

$$L_{sum} = 10 \log\left(\sum_i 10^{L_i/10}\right) \tag{10}$$

where, for sound pressure level L_p, $10^{Li/10}$ is p_i^2/p_{ref}^2, and L_i is the sound pressure level for the ith source.

A simpler and slightly less accurate method is outlined in Table 3. This method, although not exact, results in errors of 1 dB or less. The process with a series of levels may be shortened by combining the largest with the next largest, then combining this sum with the third largest, then the fourth largest, and so on until the combination of the remaining levels is 10 dB lower than the combined level. The process may then be stopped.

The procedures in Table 3 and Equation (10) are valid if the individual sound levels are not highly correlated, which is true for most sounds encountered in HVAC systems. One notable exception is the pure tone. If two or more sound signals contain pure tones at the same frequency, the pressures (amplitude and phase) should be added and the level (20 log) taken of the sum to find the sound pressure level of the two combined tones. The combined sound level is a function of not only the level of each tone (i.e., amplitude of the pressure), but also the phase difference between the tones. Combined sound levels from two tones of equal amplitude and frequency can range from zero (if the tones are 180° out of phase) up to 6 dB greater than the level of either tone (if the tones are exactly in phase). When two tones of similar amplitude are very close in frequency but not exactly the same, the combined sound level oscillates as the tones move in and out of phase. This effect creates an audible "beating" with a period equal to the inverse of the difference in frequency between the two tones.

Table 3 Combining Two Sound Levels

Difference between levels to be combined, dB	0 to 1	2 to 4	5 to 9	10 and More
Number of decibels to add to highest level to obtain combined level	3	2	1	0

Measurements of sound levels generated by individual sources are made in the presence of background noise (i.e., noise from sources other than the ones of interest). Thus, the measurement includes noise from the source and background noise. To remove background noise, the levels are unlogged and the square of the background sound pressure subtracted from the square of the sound pressure for the combination of the source and background noise [see Equation (2)]:

$$L_p(\text{source}) = 10 \log\left(10^{L(\text{comb})/10} - 10^{L(\text{bkgd})/10}\right) \tag{11}$$

where L(bkgd) is the sound pressure level of the background noise, measured with the source of interest turned off. If the difference between the levels with the source on and off is greater than 10 dB, then background noise levels are low enough that the effect of background noise on the levels measured with the source on can be ignored.

Resonances

Acoustic resonances occur in enclosures, such as a room or HVAC plenum, and mechanical resonances occur in structures, such as the natural frequency of vibration of a duct wall. Resonances occur at discrete frequencies where system response to excitation is high. To prevent this, the frequencies at which resonances occur must be known and avoided, particularly by sources of discrete-frequency tones. Avoid aligning the frequency of tonal noise with any frequencies of resonance of the space into which the noise is radiated.

At resonance, multiple reflections inside the space form a standing wave pattern (called a **mode shape**) with nodes at minimum pressure and antinodes at maximum pressure. Spacing between nodes (minimum acoustic pressure) and antinodes (maximum acoustic pressure) is one-quarter of an acoustic wavelength for the frequency of resonance.

Absorption and Reflection of Sound

Sound incident on a surface, such as a ceiling, is either absorbed, reflected, or transmitted. **Absorbed sound** is the part of incident sound that is transmitted through the surface and either dissipated (as in acoustic tiles) or transmitted into the adjoining space (as through an intervening partition). The fraction of acoustic intensity incident on the surface that is absorbed is called the **absorption coefficient** α, as defined by the following equation:

$$\alpha = I_{abs}/I_{inc} \tag{12}$$

where I_{abs} is the intensity of absorbed sound and I_{inc} is the intensity of sound incident on the surface.

The absorption coefficient depends on the frequency and angle of incident sound. In frequency bands, the absorption coefficient of nearly randomly incident sound is measured in large reverberant rooms. The difference in the rates at which sound decays after the source is turned off is measured before and after the sample is placed in the reverberant room. The rate at which sound decays is related to the total absorption in the room via the Sabine equation:

$$T_{60} = 0.161(V/A) \tag{13}$$

where

T_{60} = reverberation time (time required for average sound pressure level in room to decay by 60 dB), s
V = volume of room, m^3
A = total absorption in room, given by

$$A = \sum_i S_i \alpha_i$$

S_i = surface area for ith surface, m^2
α_i = absorption coefficient for ith surface

Licensed for single user. © 2021 ASHRAE, Inc.

Just as for absorption coefficients, reverberation time varies with frequency.

For sound to be incident on surfaces from all directions during absorption measurement, the room must be reverberant so that most of the sound incident on surfaces is reflected and bounced around the room in all directions. In a **diffuse sound field**, sound is incident on the absorbing sample equally from all directions. The Sabine equation applies only in a diffuse field.

Reflected sound superimposes on the incident sound, which increases the level of sound at and near the surfaces (i.e., the sound level near a surface is higher than those away from the surface in the free field). Because the energy in the room is related to the free-field sound pressure levels (see the section on Determining Sound Power for a discussion of free fields) and is often used to relate the sound power emitted into the room and the room's total absorption, it is important that sound pressure level measurements not be made close to reflecting surfaces, where the levels will be higher than in the free field. Measurements should be made at least one-quarter of a wavelength from the nearest reflecting surface (i.e., at a distance of $d \approx \lambda/4 \approx 85/f$, where d is in metres and f is frequency in Hz).

Room Acoustics

The characteristics of sound radiated into a room are affected by surfaces in the room that might absorb, reflect, or transmit sound. The changes of primary concern are the increase in sound levels from those that would exist without the room (i.e., in the open) and reverberation. Lower absorption leads to higher sound pressure levels away from the sources of noise (see the section on Sound Transmission Paths). With lower absorption, reverberation times may be longer. Reverberation can affect perception of music (e.g., in a concert hall) and speech intelligibility (e.g., in a lecture hall). Thus, when adding absorption to reduce a room's background HVAC-generated noise levels, it is important to be aware of the added absorption's effect on reverberation in the room.

Acoustic Impedance

Acoustic impedance z_a is the ratio of acoustic pressure p to particle velocity v:

$$z_a = p/v \tag{14}$$

For a wave propagating in free space far (more than ~1 m) from a source, the acoustic impedance is

$$z_a \approx \rho_0 c \tag{15}$$

where ρ_0 is the density of air (1.2 kg/m^3) and c is the sound speed in air (335 m/s).

Where acoustic impedance changes abruptly, some of the sound incident at the location of the impedance change is reflected. For example, inside an HVAC duct, the acoustic impedance is different from the free field acoustic impedance, so at the duct termination there is an abrupt change in the acoustic impedance from inside the duct to outside into the room, particularly at low frequencies. Thus, some sound inside the duct is reflected back into the duct (**end reflection**). Losses from end reflection are discussed in Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications*.

3. MEASURING SOUND

Instrumentation

The basic instrument for measuring sound is a **sound level meter**, which comprises a microphone, electronic circuitry, and a display device. The microphone converts sound pressure at a point to an electronic signal, which is then processed and the sound pressure level displayed using analog or digital circuitry. Sound level meters are usually battery-operated, light, handheld units with outputs that vary in complexity depending on cost and level of technology.

Time Averaging

Most sounds are not constant; pressure fluctuates from moment to moment and the level can vary quickly or slowly. Sound level meters can show time fluctuations of the sound pressure level using specified time constants (slow, fast, impulse), or can hold the maximum or minimum level recorded during some specified interval. All sound level meters perform some kind of time averaging. Some integrating sound level meters take an average of the sound pressure level over a user-definable time, then hold and display the result. The advantage of an integrating meter is that it is easier to read and more repeatable (especially if the measurement period is long). The quantity measured by the integrating sound level meter is the **equivalent continuous sound pressure level L_{eq}**, which is the level of the time average of the squared pressure:

$$L_{eq} = 10 \log \left[\frac{1}{T} \int_0^T \frac{p^2(t)}{p_{ref}^2} dt \right] \tag{16}$$

where $1/T \int_0^T dt$ is the time average (i.e., the sum $\int_0^T dt$ divided by the time over which the sum is taken).

Spectra and Analysis Bandwidths

Real sounds are much more complex than simple pure tones, where all the energy is at a single frequency. **Broadband sound** contains energy that usually covers most of the audible frequency range. Sometimes there are multiple, harmonically related tones. All sounds, however, can be represented as levels as a function of frequency using **frequency** or **spectral analysis**.

A **constant-bandwidth analysis** expresses a sound's energy content as a spectrum where each data point represents the same spectral width in frequency (e.g., 1 Hz). This is useful when an objectionable sound contains strong tones and the tones' frequencies must be accurately identified before remedial action is taken. A constant-bandwidth spectrum usually contains too much information for typical noise control work or for specifications of acceptable noise levels.

Measurements for most HVAC noise control work are usually made with filters that extract the energy in either **octave** or **one-third octave bands.** An octave band is a frequency band with an upper frequency limit twice that of its lower frequency limit. Octave and 1/3 octave bands are identified by their respective center frequencies, which are the geometric means of the upper and lower band limits (ANSI *Standards* S1.6 and S1.11):

$$f_c = \sqrt{f_{upper} f_{lower}}$$

Three 1/3 octave bands make up an octave band. Table 4 lists the upper, lower, and center frequencies for the preferred series of octave and 1/3 octave bands. For most HVAC sound measurements, filters for the range 20 to 5000 Hz are usually adequate.

Although octave band analysis is usually acceptable for rating acoustical environments in rooms, 1/3 octave band analysis is often useful in product development, in assessing transmission losses through partitions, and for remedial investigations.

Some sound level meters have standard broadband filters that simulate the frequency response to sound of the average human ear. The **A-weighting** filter, which simulates the response of the human ear to low levels of sound, is the most common (Figure 1 and Table 5). It deemphasizes the low-frequency portions of a sound spectrum, automatically compensating for the lower sensitivity of the human ear to low-frequency sounds.

The **C-weighting** filter weights the sound less as a function of frequency than the A-weighting, as shown in Figure 1. Because sound levels at low frequencies are attenuated by A-weighting but not by

Licensed for single user. © 2021 ASHRAE, Inc.

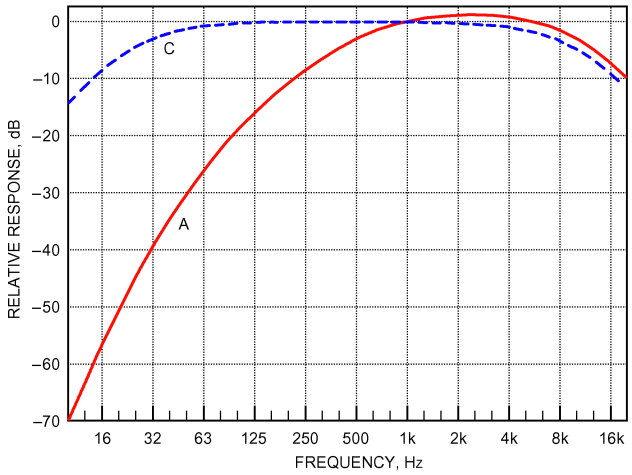

Fig. 1 Curves Showing A- and C-Weighting Responses for Sound Level Meters

			18 000	20 000	22 400

C-weighting, these weightings can be used to estimate whether a particular sound has excessive low-frequency energy when a spectrum analyzer is not available. If the difference between C- and A-weighted levels for the sound exceeds about 20 dB, then the sound is likely to be annoying because of excessive low-frequency noise.

Table 5 A-Weighting for 1/3 Octave and Octave Bands

Table 6 Combining Decibels to Determine Overall Sound Pressure Level

Octave Band Frequency, Hz	Octave Band Level L_p, dB	$10^{L_p/10}$		
63	85	3.2×10^8	=	0.32×10^9
125	90	1.0×10^9	=	1.0×10^9
250	92	1.6×10^9	=	1.6×10^9
500	87	5.0×10^8	=	0.5×10^9
1000	82	1.6×10^8	=	0.16×10^9
2000	78	6.3×10^7	=	0.06×10^9
4000	65	3.2×10^6	=	0.003×10^9
8000	54	2.5×10^5	=	0.0002×10^9
				3.6432×10^9
				$10 \log (3.6 \times 10^9) = 96$ dB

Note that C-weighting provides some attenuation at very low and very high frequencies: C-weighting is not the same as no weighting (i.e., flat weighting).

Sound level meters are available in several accuracy grades specified by ANSI *Standard* S1.4. A type 1 meter has an accuracy of about ±1.0 dB from 50 to 4000 Hz. The general-purpose type 2 meter, which is less expensive, has a tolerance of about ±1.5 dB from 100 to 1000 Hz, and is adequate for most HVAC sound measurements.

Manually selecting filters sequentially to cover the frequency range from 20 to 5000 Hz is time consuming. An instrument that gives all filtered levels simultaneously is called a **real-time analyzer (RTA)**. It speeds up measurement significantly, and most models can save information to an internal or external digital storage device.

The process described in Equation (10) for adding a series of levels can be applied to a set of octave or 1/3 octave bands to calculate the overall broadband level (see Table 6 for an example). The

Licensed for single user. © 2021 ASHRAE, Inc.

A-weighted sound level may be estimated using octave or 1/3 octave band levels by adding A-weightings given in Table 5 to octave or 1/3 octave band levels before combining the levels.

Sound Measurement Basics

The sound pressure level in an occupied space can be measured directly with a sound level meter, or estimated from published sound power data after accounting for room volume, distance from the source, and other acoustical factors (see the section on Sound Transmission Paths). Sound level meters measure sound pressure at the microphone location. Estimation techniques calculate sound pressure at a specified point in an occupied space. Measured or estimated sound pressure levels in frequency bands can then be plotted, analyzed, and compared with established criteria for acceptance.

Sound measurements must be done carefully to ensure repeatable and accurate results. Note that equipment noise varies significantly with the operation conditions. To make proper comparisons, HVAC unit conditions must be controlled under a reference condition (e.g., full load). Even so, sound levels may not be steady, particularly at low frequencies (250 Hz and lower), and can vary significantly with time. In these cases, both maximum (as measured on a meter with slow response) and average levels (over intervals established by various standards) should be recorded. Other important considerations for sound measurement procedures include

- Ambient sound pressure level with HVAC equipment off, with correction factors when HVAC levels are not significantly above ambient
- Number of locations for measurements, based on room volume, occupancy, etc.
- Duration of time-averaged measurements, statistical meter settings, etc.

Sophisticated sound measurements and their procedures should be carried out by individuals experienced in acoustic measurements. At present, there are only a few noise standards that can be used to measure interior sound levels from mechanical equipment (e.g., ASTM *Standards* E1573 and E1574). Most manuals for sound level meters include sections on how to measure sound, but basic methods that can help obtain acceptable measurements are included here.

Determining the sound spectrum in a room or investigating a noise complaint usually requires measuring sound pressure levels in the octave bands from 16 to 8000 Hz. In cases where tonal noise or rumble is the complaint, narrow-band or 1/3 octave band measurements are recommended because of their greater frequency resolution. Whatever the measurement method, remember that sound pressure levels can vary significantly from point to point in a room. In a room, each measurement point often provides a different value for sound pressure level, so the actual location of measurement is very important and must be detailed in the report. A survey could record the location and level of the loudest position, or could establish a few representative locations where occupants are normally situated. In general, the most appropriate height is 1.2 to 1.8 m above the floor. Avoid the exact geometric center of the room and any location within 1 m of a wall, floor, or ceiling. Wherever the location, it must be defined and recorded. If the meter has an integrating-averaging function, use a rotating boom to sample a large area, or slowly walk around the room, and the meter will determine the average sound pressure level for that path. However, take care that no extraneous sounds are generated by microphone movement or by walking; using a windscreen reduces extraneous noise generated by airflow over the moving microphone. Locations with noticeably higher-than-average sound levels should be recorded. See the section on Measurement of Room Sound Pressure Level for more details.

When measuring HVAC noise, **background noise** from other sources (occupants, wind, nearby traffic, elevators, etc.) must be determined. Sometimes the sound from a particular piece of HVAC equipment must be measured in the presence of background sound from sources that cannot be turned off, such as automobile traffic or certain office equipment. Determining the sound level of just the selected equipment requires making two sets of measurements: one with both the HVAC equipment sound and background sound, and another with only the background sound (with HVAC equipment turned off). This situation might also occur, for example, when determining whether noise exposure at the property line from a cooling tower meets a local noise ordinance.

Table 7 Guidelines for Determining Equipment Sound Levels in the Presence of Contaminating Background Sound

Measurement A minus Measurement B	Correction to Measurement A to Obtain Equipment Sound Level
10 dB or more	0 dB
6 to 9 dB	–1 dB
4 to 5 dB	–2 dB
Less than 4 dB	Equipment sound level is more than 2 dB below Measurement A

Measurement A = Tested equipment plus background sound
Measurement B = Background sound alone

The guidelines in Table 7 help determine the sound level of a particular machine in the presence of background sound. Equation (11) in the section on Combining Sound Levels may be used.

The uncertainty associated with correcting for background sound depends on the uncertainty of the measuring instrument and the steadiness of the sounds being measured. In favorable circumstances, it might be possible to extend Table 7. In particularly unfavorable circumstances, even values obtained from the table could be substantially in error.

Measuring sound emissions from a particular piece of equipment or group of equipment requires a measurement plan specific to the situation. The Air-Conditioning, Heating, and Refrigeration Institute (AHRI); Air Movement and Control Association International (AMCA); American Society of Testing and Materials (ASTM); American National Standards Institute (ANSI); and Acoustical Society of America (ASA) all publish sound level measurement procedures for various laboratory and field sound measurement situations.

Outdoor measurements are somewhat easier to make than indoor because there are typically few or no boundary surfaces to affect sound build-up or absorption. Nevertheless, important issues such as the effect of large, nearby sound-reflecting surfaces and weather conditions such as wind, temperature, and precipitation must be addressed. Where measurements are made close to extended surfaces (i.e., flat or nearly flat surfaces with dimensions more than four times the wavelength of the sound of interest), sound pressure levels can be significantly increased. These effects can be estimated through guidelines in many sources such as Harris (1991).

Measurement of Room Sound Pressure Level

In commissioning building HVAC systems, often a specified room noise criterion must demonstratively be met. Measurement procedures for obtaining the data to demonstrate compliance should also be specified to avoid confusion when different parties make measurements using different procedures. The problem is that most rooms exhibit significant point-to-point variation in sound pressure level.

When a noise has no audible tonal components, differences in measured sound pressure level at several locations in a room may be as high as 3 to 5 dB. However, when audible tonal components are present, especially at low frequencies, variations caused by standing waves that occur at frequencies of resonance may exceed 10 dB.

Licensed for single user. © 2021 ASHRAE, Inc.

These are generally noticeable to the average listener when moving through the room.

Although commissioning procedures usually set precise limits for demonstrating compliance, the outcome can unfortunately be controversial unless the measurement procedure has been specified in detail. In the absence of firm agreement in the industry on an acoustical measurement procedure for commissioning HVAC systems, possibilities include the new ANSI *Standard* S12.72-2015 on measuring ambient noise levels in a room, as well as AHRI *Standard* 885, which incorporates a "suggested procedure for field verification of NC/RC levels."

Measurement of Acoustic Intensity

Equation (8) for the time-averaged intensity (often called simply *intensity*) requires both the pressure and particle velocity. Pressure is easily measured with a microphone, but there is no simple transducer that converts particle velocity to a measurable electronic signal. Fortunately, particle velocity can be estimated from sound pressures measured at closely spaced (less than ~1/10 of an acoustic wavelength) locations, using Euler's equation:

$$v = -\frac{1}{i2\pi f\rho_0} \times \frac{\partial p}{\partial x} \approx -\frac{1}{i2\pi f\rho_0} \times \frac{p_2 - p_1}{x_2 - x_1} \tag{17}$$

where x_2 and x_1 are the locations of measurements of pressures p_2 and p_1, f is frequency in Hz, and ρ_0 is density of air. The spatial derivative of pressure ($\partial p/\partial x$) is approximated with ($\Delta p/\Delta x$) = $[(p_2 - p_1)/(x_2 - x_1)]$. Thus, intensity probes typically contain two closely spaced microphones that have nearly identical responses (i.e., are phase matched). Because intensity is a vector, it shows the direction of sound propagation along the line between the microphones, in addition to the magnitude of the sound. Also, because intensity is power/area, it is not sensitive to the acoustic nearfield (see the section on Typical Sources of Sound) or to standing waves where the intensity is zero. Therefore, unlike pressure measurement, intensity measurements can be made in the acoustic nearfield of a source or in the reverberant field in a room to determine the power radiated from the source. However, intensity measurements cannot be used in a diffuse field to determine the acoustic energy in the field, such as used for determining sound power using the reverberation room method.

4. DETERMINING SOUND POWER

The sound power of a source cannot be measured directly. Rather, it is calculated from several measurements of sound pressure or sound intensity created by a source in one of several test environments. The following four methods are commonly used.

Free-Field Method

A **free field** is a sound field where the effects of any boundaries are negligible over the frequency range of interest. In ideal conditions, there are no boundaries. Free-field conditions can be approximated in rooms with highly sound-absorbing walls, floor, and ceiling (**anechoic rooms**). In a free field, the sound power of a sound source can be determined from measurements of sound pressure level on an imaginary spherical surface centered on and surrounding the source. This method is based on the fact that, because sound absorption in air can be practically neglected at small distances from the sound source, all of the sound power generated by a source must flow through an imagined sphere with the source at its center. The intensity I of the sound (conventionally expressed in W/m^2) is estimated from measured sound pressure levels using the following equation:

$$I = (1 \times 10^{-12})10^{L_p/10} \tag{18}$$

where L_p is sound pressure level. The intensity at each point around the source is multiplied by that portion of the area of the imagined sphere associated with the measuring points. Total sound power W is the sum of these products for each point:

$$W = \sum_i I_i A_i \tag{19}$$

where A_i is the surface area (in m^2) associated with the ith measurement location.

ANSI *Standard* S12.55 describes various methods used to calculate sound power level under free-field conditions. Measurement accuracy is limited at lower frequencies by the difficulty of obtaining room surface treatments with high sound absorption coefficients at low frequencies. For example, a glass fiber wedge structure that gives significant absorption at 70 Hz must be at least 1.2 m long.

The relationship between sound power level L_w and sound pressure level L_p for a nondirectional sound source in a free field at distance r in metres can be written as

$$L_w = L_p + 20 \log r + 11 \tag{20}$$

For directional sources, use Equation (19) to compute sound power.

Often, a completely free field is not available, and measurements must be made in a free field over a reflecting plane. This means that the sound source is placed on a hard floor (in an otherwise sound-absorbing room) or on smooth, flat pavement outdoors. Because the sound is then radiated into a hemisphere rather than a full sphere, the relationship for L_w and L_p for a nondirectional sound source becomes

$$L_w = L_p + 20 \log r + 8 \tag{21}$$

A sound source may radiate different amounts of sound power in different directions. A directivity pattern can be established by measuring sound pressure under free-field conditions, either in an anechoic room or over a reflecting plane in a hemianechoic space at several points around the source. The directivity factor Q is the ratio of the squared sound pressure at a given angle from the sound source to the squared sound pressure that would be produced by the same source radiating uniformly in all directions. Q is a function of frequency and direction. The section on Typical Sources of Sound in this chapter and Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* provide more detailed information on sound source directivity.

Reverberation Room Method

Another method to determine sound power places the sound source in a reverberation room. AHRI *Standard* 220 and ANSI *Standard* S12.58 give standardized methods for determining the sound power of HVAC equipment in reverberation rooms when the sound source contains mostly broadband sound or when tonal sound is prominent. These standards provide a method of qualifying the room to verify that sound power levels for both broadband and tonal noise sources can be accurately determined.

Some sound sources that can be measured by these methods are room air conditioners, refrigeration compressors, components of central HVAC systems, and air terminal devices. For ducted equipment, AHRI *Standard* 261 provides a method of test and AHRI *Standards* 270 and 370 provide test methods for measuring outdoor equipment. Compressors should be tested according to AHRI *Standard* 530. ANSI/ASHRAE *Standard* 130, and ANSI/AHRI *Standard* 881-2011 establish special measuring procedures for some of these units. AMCA *Standard* 300 is appropriate for testing fans that are not incorporated into equipment.

Two measurement methods may be used in reverberation rooms: direct and substitution. In **direct reverberation room measurement**, the sound pressure level is measured with the source in the

Licensed for single user. © 2021 ASHRAE, Inc.

reverberation room at several locations at a distance of at least 1 m from the source and at least one-quarter of a wavelength from the surfaces of the room. The sound power level is calculated from the average of the sound pressure levels, using the reverberation time and the volume of the reverberation room.

The relationship between sound power level and sound pressure level in a reverberation room is given by

$$L_w = L_p + 10 \log V - 10 \log T_{60} - 14 \quad (22)$$

where

L_p = sound pressure level averaged over room, dB re 20 μPa
V = volume of room, m^3
T_{60} = room reverberation time (time required for a 60 dB decay), s

The **substitution** procedure implemented in most ASHRAE, AHRI, and AMCA test standards uses a calibrated **reference sound source (RSS)**. The sound power levels of noise radiated by an RSS are known by calibration using the free-field method or, in the case of AHRI *Standard* 250-2013, a hemi-anechoic room method.

The most common RSS is a small, vertically shafted direct-drive fan impeller that has no volute housing or scroll. The forward-curved impeller has a choke plate on its inlet face, causing the fan to operate in a rotating-stall condition that is very noisy. The reference source is designed to have a stable sound power level output from 63 to 8000 Hz and a relatively uniform frequency spectrum in each octave band.

Sound pressure level measurements are first made in the reverberant field (far from the RSS or source in question) with only the reference sound source operating in the test room. Then the reference source is turned off and the measurements are repeated with the given source in operation. Because the acoustical environment and measurement locations are the same for both sources, the differences in sound pressure levels measured represent differences in sound power level between the two sources.

Using this method, the relationship between sound power level and sound pressure level for the two sources is given by

$$L_w = L_p + (L_w - L_p)_{ref} \quad (23)$$

where

L_p = sound pressure level averaged over room, dB re 20 μPa
$(L_w - L_p)_{ref}$ = difference between sound power level and sound pressure level of reference sound source

Progressive Wave (In-Duct) Method

By attaching a fan to one end of a duct, sound energy is confined to a progressive wave field in the duct. Fan sound power can then be determined by measuring the sound pressure level inside the duct. Intensity is then estimated from the sound pressure levels (see the section on the Free-Field Method) and multiplied by the cross-sectional area of the duct to find the sound power. The method is described in detail in ASHRAE *Standard* 68 (AMCA *Standard* 330) for in-duct testing of fans. This method is not commonly used because of difficulties in constructing the required duct termination and in discriminating between fan noise and flow noise caused by the presence of the microphone in the duct.

Sound Intensity Method

The average sound power radiated by the source can be determined by measuring the sound intensity over the sphere or hemisphere surrounding a sound source (see the sections on Measurement of Acoustic Intensity and on the Free-Field Method). One advantage of this method is that, with certain limitations, sound intensity (and therefore sound power) measurements can be made in the presence of steady background noise in semireverberant environments and in the acoustic nearfield of sources. Another advantage is that by measuring sound intensity over surfaces that enclose a sound source, sound directivity can be determined. Also, for large sources, areas of radiation can be localized using intensity measurements. This procedure can be particularly useful in diagnosing sources of noise during product development.

International and U.S. standards that prescribe methods for making sound power measurements with sound intensity probes consisting of two closely spaced microphones include ANSI *Standard* S12.12 and ISO *Standards* 9614-1 and 9614-2. In some situations, the sound fields may be so complex that measurements become impractical. A particular concern is that small test rooms or those with somewhat flexible boundaries (e.g., sheet metal or thin drywall) can increase the radiation impedance for the source, which could affect the source's sound power output.

Measurement Bandwidths for Sound Power

Sound power is normally determined in octave or 1/3 octave bands. Occasionally, more detailed determination of the sound source spectrum is required: **narrowband analysis**, using either constant fractional bandwidth (1/12 or 1/24 octave) or constant absolute bandwidth (e.g., 1 Hz). The most frequently used analyzer types are digital filter analyzers for constant-percent bandwidth measurements and fast Fourier transform (FFT) analyzers for constant-bandwidth measurements. Narrowband analyses are used to determine the frequencies of pure tones and their harmonics in a sound spectrum.

5. CONVERTING FROM SOUND POWER TO SOUND PRESSURE

Designers are often required to use sound power level information of a source to predict the sound pressure level at a given location. Sound pressure at a given location in a room from a source of known sound power level depends on (1) room volume, (2) room furnishings and surface treatments, (3) magnitude of sound source(s), (4) distance from sound source(s) to point of observation, and (5) directivity of source.

The classic relationship between a single-point source sound power level and room sound pressure level at some frequency is

$$L_p = L_w + 10 \log(Q/4\pi r^2 + 4/R) \quad (24)$$

where

L_p = sound pressure level, dB re 20 μPa
L_w = sound power level, dB re 10^{-12} W
Q = directivity of sound source (dimensionless)
r = distance from source, m
R = room constant, $S\alpha/(1 - \alpha)$
S = sum of all surface areas, m^2
α = average absorption coefficient of room surfaces at given frequency, given by

$$\sum_i S_i \alpha_i / \sum_i S_i$$

where S_i is area of ith surface and α_i is absorption coefficient for ith surface.

If the source is outdoors, far from reflecting surfaces, this relationship simplifies to

$$L_p = L_w + 10 \log(Q/4\pi r^2) \quad (25)$$

This relationship does not account for atmospheric absorption, weather effects, and barriers. Note that r^2 is present because the sound pressure in a free field decreases with $1/r^2$ (the inverse-square law; see the section on Sound Transmission Paths). Each time the distance from the source is doubled, the sound pressure level decreases by 6 dB.

For a simple source centered in a large, flat, reflecting surface, Q may be taken as 2. At the junction of two large flat surfaces, Q is 4; in a corner, Q is 8.

Licensed for single user. © 2021 ASHRAE, Inc.

In most typical rooms, the presence of acoustically absorbent surfaces and sound-scattering elements (e.g., furniture) creates a relationship between sound power and sound pressure level that is difficult to predict. For example, hospital rooms, which have only a small amount of absorption, and executive offices, which have substantial absorption, are similar when the comparison is based on the same room volume and distance between the source and point of observation.

Using a series of measurements taken in typical rooms, Equation (26) was developed to estimate the sound pressure level at a chosen observation point in a normally furnished room. The estimate is accurate to ±2 dB (Schultz 1985).

$$L_p = L_w - 5 \log V - 3 \log f - 10 \log r + 12 \quad (26)$$

Equation (26) applies to a single sound source in the room itself, not to sources above the ceiling. With more than one source, total sound pressure level at the observation point is obtained by adding the contribution from each source in energy or power-like units, not decibels, and then converting back to sound pressure level [see Equation (10)]. Studies (Warnock 1997, 1998a, 1998b) indicate that sound sources above ceilings may not act as point sources, and Equation (26) may not apply (AHRI *Standard* 885).

6. SOUND TRANSMISSION PATHS

Sound from a source is transmitted along one or more paths to a receiver. Airborne and structureborne transmission paths are both of concern for the HVAC system designer. Sound transmission between rooms occurs along both airborne and structureborne transmission paths. Chapter 49of the 2019 *ASHRAE Handbook—HVAC Applications* has additional information on transmission paths.

Spreading Losses

In a free field, the intensity I of sound radiated from a single source with dimensions that are not large compared to an acoustic wavelength is equal to the power W radiated by the source divided by the surface area A (expressed in m^2) over which the power is spread:

$$I = W/A \quad (27)$$

In the absence of reflection, the spherical area over which power spreads is $A = 4\pi r^2$, so that the intensity is

$$I = W/4\pi r^2 \quad (28)$$

where r is the distance from the source in metres. Taking the level of the intensity (i.e., 10 log) and using Equation (20) to relate intensity to sound pressure levels leads to

$$L_p = L_w - 10 \log(4\pi r^2) \quad (29)$$

which becomes

$$L_p = L_w - 20 \log r - 11 = L_w - 10 \log(r^2) - 11 \quad (30)$$

Thus, the sound pressure level decreases as $10 \log(r^2)$, or 6 dB per doubling of distance. This reduction in sound pressure level of sound radiated into the free field from a single source is called **spherical spreading loss**.

Direct Versus Reverberant Fields

Equation (24) relates the sound pressure level L_p in a room at distance r from a source to the sound power level L_w of the source. The first term in the brackets ($Q/4\pi r^2$) represents sound radiated directly from the source to the receiver, and includes the source's directivity Q and the spreading loss $1/4\pi r^2$ from the source to the observation location. The second term in the brackets, $4/R$, represents the reverberant field created by multiple reflections from room surfaces. The room constant is

$$R = \frac{\sum_i S_i \alpha_i}{1 - \bar{\alpha}} \quad (31)$$

where $\bar{\alpha}$ is the spatial average absorption coefficient,

$$\bar{\alpha} = \frac{\sum_i S_i \alpha_i}{\sum_i S_i} \quad (32)$$

At distances close enough to the source that $Q/4\pi r^2$ is larger than $4/R$, the direct field is dominant and Equation (24) can be approximated by

$$L_p = L_w + 10 \log\left(\frac{Q}{4\pi r^2}\right) \quad (33)$$

Equation (33) is independent of room absorption R, which indicates that adding absorption to the room will not change the sound pressure level. At distances far enough from the source that $Q/4\pi r^2$ is less than $4/R$, Equation (24) can be approximated by

$$L_p = L_w + 10 \log\left(\frac{4}{R}\right) = L_w - 10 \log R + 6 \quad (34)$$

Adding absorption to the room increases the room constant and thereby reduces the sound pressure level. The reduction in reverberant sound pressure levels associated with adding absorption in the room is approximated by

$$\text{Reduction} \approx 10 \log\left(\frac{R_2}{R_1}\right) \quad (35)$$

where R_2 is the room constant for the room with added absorption and R_1 is the room constant for the room before absorption is added. The distance from the source where the reverberant field first becomes dominant such that adding absorption to the room is effective is the critical distance r_c, obtained by setting $Q/4\pi r^2 = 4/R$. This leads to

$$r_c \approx 0.14 \sqrt{QR} \quad (36)$$

where R is in m^2 and r_c is in m.

Airborne Transmission

Sound transmits readily through air, both indoors and outdoors. Indoor sound transmission paths include the direct line of sight between the source and receiver, as well as reflected paths introduced by the room's walls, floor, ceiling, and furnishings, which cause multiple sound reflection paths.

Outdoors, the effects of the reflections are small, unless the source is located near large reflecting surfaces. However, wind and temperature gradients can cause sound outdoors to refract (bend) and change propagation direction. Without strong wind and temperature gradients and at small distances, sound propagation outdoors follows the inverse square law. Therefore, Equations (20) and (21) can generally be used to calculate the relationship between sound power level and sound pressure level for fully free-field and hemispherical free-field conditions, respectively.

Ductborne Transmission

Ductwork can provide an effective sound transmission path because the sound is primarily contained within the boundaries of

Licensed for single user. © 2021 ASHRAE, Inc.

the ductwork and thus suffers only small spreading losses. Sound can transmit both upstream and downstream from the source. A special case of ductborne transmission is **crosstalk**, where sound is transmitted from one room to another via the duct path. Where duct geometry changes abruptly (e.g., at elbows, branches, and terminations), the resulting change in the acoustic impedance reflects sound, which increases propagation losses. Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* has additional information on losses for airborne sound propagation in ducts.

Room-to-Room Transmission

Room-to-room sound transmission generally involves both airborne and structureborne sound paths. The sound power incident on a room surface element undergoes three processes: (1) some sound energy is reflected from the surface element back into the source room, (2) a portion of the energy is lost through energy transfer into the material comprising the surface element, and (3) the remainder is transmitted through the surface element to the other room. Airborne sound is radiated as the surface element vibrates in the receiving room, and structureborne sound can be transmitted via the studs of a partition or the floor and ceiling surfaces.

Structureborne Transmission

Solid structures are efficient transmission paths for sound, which frequently originates as a vibration imposed on the transmitting structure. Typically, only a small amount of the input energy is radiated by the structure as airborne sound. With the same force excitation, a low-mass structure with little inherent damping radiates more sound than a massive structure with greater damping.

Flanking Transmission

Sound from the source room can bypass the primary separating element and get into the receiving room along other paths, called **flanking paths**. Common sound flanking paths include return air plenums, doors, and windows. Less obvious paths are those along floor and adjoining wall structures. Such flanking paths can reduce sound isolation between rooms. Flanking can explain poor sound isolation between spaces when the partition between them is known to provide very good sound insulation, and how sound can be heard in a location far from the source in a building. Determining whether flanking sound transmission is important and what paths are involved can be difficult. Experience with actual situations and the theoretical aspects of flanking transmission is very helpful. Sound intensity methods may be useful in determining flanking paths.

7. TYPICAL SOURCES OF SOUND

Whenever mechanical power is generated or transmitted, a fraction of the power is converted into sound power and radiated into the air. Therefore, virtually any major component of an HVAC system could be considered a sound source (e.g., fans, pumps, ductwork, piping, motors). The component's sound source characteristics depend on its construction, form of mechanical power, and integration with associated system components. The most important source characteristics include total sound power output L_w, frequency distribution, and radiation directivity Q. In addition, a vibrating HVAC system may be relatively quiet but transmit noise to connecting components, such as the unit casing, which may be serious sources of radiated noise. All of these characteristics vary with frequency.

Source Strength

For airborne noise, source strength should be expressed in terms of sound power levels. For structureborne noise (i.e., vibration), source strengths should be expressed in terms of free vibration levels (measured with the source free from any attachments). Because it is difficult to free a source from all attachments, measurements made with the source on soft mounts, with small mechanical impedances compared to the impedance of the source, can be used to obtain good approximations to free vibration levels.

Directivity of Sources

Noise radiation from sources can be directional. The larger the source, relative to an acoustic wavelength, the greater the potential of the source to be directional. Small sources tend to be nondirectional. The directivity of a source is expressed by the directivity factor Q as

$$Q = \frac{p^2(\theta)}{p_{ave}^2} \tag{37}$$

where $p^2(\theta)$ is the squared pressure observed in direction θ and p_{ave}^2 is the energy average of the squared pressures measured over all directions.

Acoustic Nearfield

Not all unsteady pressures produced by the vibrating surfaces of a source or directly by disturbances in flow result in radiated sound. Some unsteady pressures "cling" to the surface. Their magnitude decreases rapidly with distance from the source, whereas the magnitude of radiating pressures decreases far less rapidly. The region close to the source where nonradiating unsteady pressures are significant is called the **acoustic nearfield**. Sound pressure level measurements should not be made in the acoustic nearfield because it is difficult to relate sound pressure levels measured in the nearfield to radiated levels. In general, the nearfield for most sources extends no more than 1 m from the source. However, at lower frequencies and for large sources, sound pressure level measurements should be made more than 1 m from the source when possible.

Sound and vibration sources in HVAC systems are so numerous that it is impractical to provide a complete listing here. Major sources include rotating and reciprocating equipment such as compressors, fans, motors, pumps, air-handling units, water-source heat pumps (WSHPs, often used in hotels), rooftop units, and chillers.

Noise generation occurs from many mechanisms, including

- Vortex shedding, which can be tonal, at the trailing edges of fan blades. Levels of vortex shedding noise increase with velocity of flow v_b over the blade proportionate to $\log(v_b)$.
- Turbulence generated upstream of the fan and ingested into the fan. Levels of this broadband noise increase proportionate to $\log(v_0)$, where v_0 is the free-stream velocity of flow into the fan. Turbulence in the boundary layer on the surface of fan blades also causes broadband noise that increases proportionate to $\log(v_b)$. Flow that separates from blade surfaces can cause low-frequency noise. Nonuniform inflow to fans, created by obstructions, can produce tonal noise at frequencies of blade passage ($f_b = Nf_r$, where N is the number of blades and f_r is the rotation speed in rev/s) and integer multiples. Fan imbalance produces vibration at frequencies of shaft rotation and multiples. These low-frequency vibrations can couple to the structures to which the fan is attached, which can transmit the vibration over long distances and radiate low-frequency noise into rooms.
- Air and fluid sounds, such as those associated with flow through ductwork, piping systems, grilles, diffusers, terminal boxes, manifolds, and pressure-reducing stations.
- Turbulent flow inside ducts, which is a source of broadband noise. Levels increase proportionate to $\log(v_0)$. Sharp corners of elbows and branches can separate flow from duct walls, producing low-frequency noise.
- Excitation of surfaces (e.g., friction); movement of mechanical linkages; turbulent flow impacts on ducts, plenum panels, and pipes; and impacts within equipment, such as cams and valve

Licensed for single user. © 2021 ASHRAE, Inc.

slap. Broadband flow noise increases rapidly with flow velocity v [60 to 80 log (v)], so reducing flow velocities can be very effective in reducing broadband noise.
- Magnetostriction (transformer hum), which becomes significant in motor laminations, transformers, switchgear, lighting ballasts, and dimmers. A characteristic of magnetostrictive oscillations is that their fundamental frequency is twice the electrical line frequency (120 Hz in a 60 Hz electrical distribution system.)

8. CONTROLLING SOUND

Terminology

The following noninterchangeable terms are used to describe the acoustical performance of many system components. ASTM *Standard* C634 defines additional terms.

Sound attenuation is a general term describing the reduction of the level of sound as it travels from a source to a receiver.

Insertion loss (IL) of a silencer or other sound-attenuating element, expressed in dB, is the decrease in sound pressure level or sound intensity level, measured at a fixed receiver location, when the sound-attenuating element is inserted into the path between the source and receiver. For example, if a straight, unlined piece of ductwork were replaced with a duct silencer, the sound level difference at a fixed location would be considered the silencer's insertion loss. Measurements are typically in either octave or 1/3 octave bands.

Sound transmission loss (TL) of a partition or other building element is equal to 10 times the logarithm of the ratio of the airborne sound power incident on the partition to the sound power transmitted by the partition and radiated on the other side, in decibels. Measurements are typically in octave or 1/3 octave bands. Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* defines the special case of breakout transmission loss through duct walls.

Noise reduction (NR) is the difference between the space-average sound pressure levels produced in two enclosed spaces or rooms (a receiving room and a source room) by one or more sound sources in the source room. An alternative, non-ASTM definition of NR is the difference in sound pressure levels measured upstream and downstream of a duct silencer or sound-attenuating element. Measurements are typically in octave or 1/3 octave bands. For partitions, NR is related to the transmission loss TL as follows:

$$\mathrm{NR} = \mathrm{TL} - 10 \log\left(\frac{S}{R}\right) \tag{38}$$

where S is the partition's surface area and R is the room constant for the receiving room. Note that sound pressure levels measured close to the partition on the receiving side may be higher and should not be included in the space average used to compute the noise reduction.

Random-incidence sound absorption coefficient α is the fraction of incident sound energy absorbed by a surface exposed to randomly incident sound. It is measured in a reverberation room using 1/3 octave bands of broadband sound (ASTM *Standard* C423). The sound absorption coefficient of a material in a specific 1/3 octave band depends on the material's thickness, airflow resistivity, stiffness, and method of attachment to the supporting structure.

Scattering is the change in direction of sound propagation caused by an obstacle or inhomogeneity in the transmission medium. It results in the incident sound energy being dispersed in many directions.

Enclosures and Barriers

Enclosing a sound source is a common means of controlling airborne radiation from a source. Enclosure performance is expressed in terms of insertion loss. The mass of the enclosure panels combines with the stiffness (provided by compression) of the air trapped between the source and enclosure panel to produce a resonance. At resonance, the insertion loss may be negative, indicating that radiated noise levels are higher with the enclosure than without it. Therefore, the enclosure design should avoid aligning the enclosure resonance with frequencies commonly radiated from the source at high levels. At low frequencies, insertion loss of enclosures is more sensitive to stiffness of the enclosure panels than to the surface mass density of the panels. At high frequencies, the opposite is true.

The insertion loss of an enclosure may be severely compromised by openings or leaks. All penetrations must be sealed. Also, at higher frequencies, adding an enclosure creates a reverberant space between the outer surfaces of the source and the inner surfaces of the enclosure. To avoid build-up of reverberant noise, and thereby noise transmitted through the enclosure, add absorption inside the enclosure.

A barrier is a solid element that blocks line-of-sight transmission but does not totally enclose the source or receiver. Properly designed barriers can effectively block sound that propagates directly from the source to the receiver. Barrier performance is expressed in terms of insertion loss: in general, the greater the increase in the path over or around the barrier relative to the direct path between the source and receiver without the barrier, the greater the barrier's insertion losses. Thus, placing the barrier close to the source or receiver is better than midway between the two. The barrier must break the line of sight between the source and receiver to be effective. Insertion losses increase as the barrier extends further above the line of sight. Barriers are only effective in reducing levels for sound propagated directly from the source to the receiver; they do not reduce levels of sound reflected from surfaces in rooms that bypass the barrier. Therefore, barriers are less effective in reverberant spaces than in nonreverberant spaces.

Partitions

Partitions are typically either single- or double-leaf. **Single-leaf partitions** are solid homogeneous panels with both faces rigidly connected. Examples are gypsum board, plywood, concrete block, brick, and poured concrete. The transmission loss of a single-leaf partition depends mainly on its surface mass (mass per unit area): the heavier the partition, the less it vibrates in response to sound waves and the less sound it radiates on the side opposite the sound source. Surface mass can be increased by increasing the partition's thickness or its density.

The **mass law** is a semiempirical expression that can predict transmission loss for randomly incident sound for thin, homogeneous single-leaf panels below the critical frequency (discussed later in this section) for the panel. It is written as

$$\mathrm{TL} = 20 \log(w_s f) - 47 \tag{39}$$

where

TL = transmission loss
w_s = surface mass of panel, kg/m^2
f = frequency, Hz

The mass law predicts that transmission loss increases by 6 dB for each doubling of surface mass or frequency. If sound is incident only perpendicularly on the panel (rarely found in real-world applications), TL is about 5 dB greater than that predicted by Equation (39).

Transmission loss also depends on stiffness and internal damping. The transmission losses of three single-leaf walls are shown in Figure 2. For 16 mm gypsum board, TL depends mainly on the surface mass of the wall at frequencies below about 1 kHz; agreement with the mass law is good. At higher frequencies, there is a dip in the TL curve called the **coincidence dip** because it occurs at the frequency where the wavelength of flexural vibrations in the wall coincides with the wavelength of sound on the panel surface. The lowest

Licensed for single user. © 2021 ASHRAE, Inc.

frequency where coincidence between the flexural and surface pressure waves can occur is called the **critical frequency** f_c:

$$f_c = \frac{c^2}{2\pi}\left(\frac{12\rho}{Eh^2}\right)^{1/2} \quad (40)$$

where

ρ = density of panel material, kg/m^3
E = Young's modulus of panel material, N/m^2
h = thickness of outer panel of partition, m
c = sound speed in air,m/s

This equation indicates that increasing the material's stiffness and/or thickness reduces the critical frequency, and that increasing the material's density increases the critical frequency. For example, the 150 mm concrete slab has a mass of about 370 kg/m^2 and has a coincidence frequency at 125 Hz. Thus, over most of the frequency range shown in Figure 2, the transmission loss for the 150 mm concrete slab is well below that predicted by mass law. The coincidence dip for the 25 gage (0.531 mm thick) steel sheet occurs at high frequencies not shown in the figure.

The **sound transmission class (STC) rating** of a partition or assembly is a single number rating often used to classify sound isolation for speech (ASTM *Standards* E90 and E413). To determine a partition's STC rating, compare transmission losses measured in 1/3 octave bands with center frequencies from 125 to 4000 Hz to the STC contour shown in Figure 3. This contour is moved up until either

- The sum of differences between TL values below the contour and the corresponding value on the contour is no more than 32, or
- One of the differences between the contour and a TL value is no greater than 8.

The STC is then the value on the contour at 500 Hz. As shown in Figure 3, the STC contour deemphasizes transmission losses at low frequencies, so the STC rating should not be used as an indicator of an assembly's ability to control sound that is rich in low frequencies. Most fan sound spectra have dominant low-frequency sound; therefore, to control fan sound, walls and slabs should be selected only on the basis of 1/3 octave or octave band sound transmission loss values, particularly at low frequencies.

Note also that sound transmission loss values for ceiling tile are inappropriate for estimating sound reduction between a sound source located in a ceiling plenum and the room below. See AHRI *Standard* 885 for guidance.

Walls with identical STC ratings may not provide identical sound insulation at all frequencies. Most single-number rating systems have limited frequency ranges, so designers should select partitions and floors based on their 1/3 octave or octave band sound transmission loss values instead, especially when frequencies below 125 Hz are important.

For a given total mass in a wall or floor, much higher values of TL can be obtained by forming a **double-leaf** construction where each layer is independently or resiliently supported so vibration transmission between them is minimized. As well as mass, TL for such walls depends on cavity depth. Mechanical decoupling of leaves reduces sound transmission through the panel, relative to the transmission that would occur with the leaves structurally connected. However, transmission losses for a double-leaf panel are less than the sum of the transmission losses for each leaf. Air in the cavity couples the two mechanically decoupled leaves. Also, resonances occur inside the cavity between the leaves, thus increasing transmission (decreasing transmission loss) through the partition. Negative effects at resonances can be reduced by adding sound-absorbing material inside the cavity. For further information, see Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Transmission losses of an enclosure may be severely compromised by openings or leaks in the partition. Ducts that lead into or through a noisy space can carry sound to many areas of a building. Designers need to consider this factor when designing duct, piping, and electrical systems.

When a partition contains two different constructions (e.g., a partition with a door), the transmission loss TL_c of the composite partition may be estimated using the following equation:

$$TL_c = 10 \log\left[\frac{S_1 + S_2}{S_1\tau_1 + S_2\tau_2}\right] \quad (41)$$

where S_1 and S_2 are the surface areas of the two types of constructions, and τ_1 and τ_2 are the transmissibilities, where $\tau = 10^{-TL/10}$. For leaks, $\tau = 1$. For a partition with a transmission of 40 dB, a hole that covers only 1% of the surface area results in a composite transmission loss of 20 dB, a 20 dB reduction in the transmission loss without the hole. This shows the importance of sealing penetrations through partitions to maintain design transmission losses.

Sound Attenuation in Ducts and Plenums

Most ductwork, even a sheet metal duct without acoustical lining or silencers, attenuates sound to some degree. The natural attenuation of unlined ductwork is minimal, but can, especially for long runs of rectangular ductwork, significantly reduce ductborne sound. Acoustic lining of ductwork can greatly attenuate sound propagation through ducts, particularly at middle to high frequencies. Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* has a detailed discussion of lined and unlined ductwork attenuation.

If analysis shows that lined ductwork will not reduce sound propagation adequately, commercially available sound attenuators (also known as **sound traps** or **duct silencers**) can be used. There are three types: dissipative, reactive, and active. The first two are commonly known as **passive attenuators**.

- **Dissipative silencers** use absorptive media such as glass or rock fiber as the principal sound-absorption mechanism. Thick, perforated sheet metal baffles filled with low-density fiber insulation restrict the air passage width within the attenuator housing. The fiber is sometimes protected from the airstream by cloths or films. This type of attenuator is most effective in reducing mid- and high-frequency sound energy.
- **Reactive silencers** (sometimes called **mufflers**) rely on changes in impedance to reflect energy back toward the source and away from the receiver. This attenuator type is typically used in HVAC systems serving hospitals, laboratories, or other areas with strict air quality standards. They are constructed only of metal, both solid and perforated. Chambers of specially designed shapes and sizes behind the perforated metal are tuned as resonators or expansion chambers to react with and reduce sound power at selected frequencies. When designed for a broad frequency range, they are usually not as effective as dissipative attenuators of the same length. However, they can be highly effective and compact if designed for a limited frequency range (e.g., for a pure tone).
- **Active silencer systems** use microphones, loudspeakers, and appropriate electronics to reduce in-duct sound by generating sound 180° out of phase that destructively interferes with the incident sound energy. Microphones sample the sound field in the duct and loudspeakers generate signals with phase opposite to the original noise. Controlled laboratory experiments have shown that active attenuators reduce both broadband and tonal sound, but are typically only effective in the 31.5 through 250 Hz octave bands. Active silencers are more effective for tonal than for broadband noise. Insertion losses of as much as 30 dB have been achieved under controlled conditions. Because the system's microphones and loudspeakers are mounted flush with the duct wall, there is no obstruction to airflow and therefore negligible pressure drop. Because active silencers are not effective in excessively turbulent airflow, their use is limited to relatively long, straight duct sections with an air velocity less than about 7.5 m/s.

Silencers are available for fans, cooling towers, air-cooled condensers, compressors, gas turbines, and many other pieces of commercial and industrial equipment. HVAC silencers are normally installed on the intake or discharge side (or both) of a fan or air-handling unit. They may also be used on the receiver side of other noise generators such as terminal boxes, valves, and dampers.

Self-noise (i.e., noise generated by airflow through the silencer) can limit an attenuator's effective insertion loss for air velocities over about 10 m/s. Sound power at the silencer outlet is a combination of the power of the noise attenuated by the silencer and the noise generated inside the silencer by flow. Thus, output power W_M is related to input power W_0 as follows:

$$W_M = W_0 10^{-IL/10} + W_{SG} \quad (42)$$

where IL is the insertion loss and W_{SG} is the power of the self-noise. It is also important to determine the dynamic insertion loss at design airflow velocity through the silencer, because a silencer's insertion loss varies with flow velocity.

End reflection losses caused by abrupt area changes in duct cross section are sometimes useful in controlling propagation at low frequencies. Low-frequency noise reduction is inversely proportional to the cross-sectional dimension of the duct, with the end reflection effect maximized in smaller cross sections and when the duct length of the smaller cross section is several duct diameters. Note, however, that abrupt area changes can increase flow velocities, which increase broadband high-frequency noise.

Where space is available, a **lined plenum** can provide excellent attenuation across a broad frequency range, especially effective at low frequencies. The combination of end reflections at the plenum's entrance and exit, a large offset between the entrance and exit, and sound-absorbing lining on the plenum walls can result in an effective sound-attenuating device.

Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* has additional information on sound control.

Standards for Testing Duct Silencers

Attenuators and duct liner materials are tested according to ASTM *Standard* E477 in North America and ISO *Standard* 7235 elsewhere. These define acoustic and aerodynamic performance in terms of dynamic insertion loss, self-noise, and airflow pressure drop. Many similarities exist, but the ASTM and ISO standards produce differing results because of variations in loudspeaker location, orientation, duct termination conditions, and computation methods. Currently, no standard test methods are available to measure attenuation by active silencers, although it is easy to measure the effectiveness simply by turning the active silencer control system on and off.

Dynamic insertion loss is measured in the presence of both forward and reverse flows. Forward flow occurs when air and sound move in the same direction, as in a supply air or fan discharge system; reverse flow occurs when air and sound travel in opposite directions, as in a return air or fan intake system.

9. SYSTEM EFFECTS

The way the HVAC components are assembled into a system affects the sound level generated by the system. Many engineers believe that satisfactory noise levels in occupied spaces can be achieved solely by using a manufacturer's sound ratings as a design tool, without considering the system influence.

However, most manufacturers' sound data are obtained under standardized (ideal) laboratory test conditions. In the field, different configurations of connected ductwork, and interactions with other components of the installation, often significantly change the operating noise level. For example, uniform flow into or out of a fan is rare in typical field applications. Nonuniform flow conditions usually increase the noise generated by fans, and are difficult to predict. However, the increases can be large (e.g., approaching 10 dB), so it is desirable to design systems to provide uniform inlet conditions. One method is to avoid locating duct turns near the inlet or discharge of a fan. Furthermore, components such as dampers and silencers installed close to fan equipment can produce nonuniformities in the velocity profile at the entrance to the silencer, which results in a significantly higher-than-anticipated pressure drop across that component. The combination of these two system effects changes the operating point on the fan curve. As a result, airflow is reduced and must be compensated for by increasing fan speed, which may increase noise. Conversely, a well-designed damper or silencer can actually improve flow conditions, which may reduce noise levels.

10. HUMAN RESPONSE TO SOUND

Noise

Noise may be defined as any unwanted sound. Sound becomes noise when it

- Is too loud: the sound is uncomfortable or makes speech difficult to understand
- Is unexpected (e.g., the sound of breaking glass)
- Is uncontrolled (e.g., a neighbor's lawn mower)
- Happens at the wrong time (e.g., a door slamming in the middle of the night)
- Contains unwanted tones (e.g., a whine, whistle, or hum)
- Contains unwanted information or is distracting (e.g., an adjacent telephone conversation or undesirable music)
- Is unpleasant (e.g., a dripping faucet)
- Connotes unpleasant experiences (e.g., a mosquito buzz or a siren wail)
- Is any combination of the previous examples

To be noise, sound does not have to be loud, just unwanted. In addition to being annoying, loud noise can cause hearing loss, and, depending on other factors, can affect stress level, sleep patterns, and heart rate.

To increase privacy, broadband sound may be radiated into a room by an electronic sound-masking system that has a random noise generator, amplifier, and multiple loudspeakers. Noise from such a system can mask low-level intrusive sounds from adjacent spaces. This controlled sound may be referred to as *noise*, but not in the context of unwanted sound; rather, it is a broadband, neutral sound that is frequently unobtrusive. It is difficult to design air-conditioning systems to produce noise that effectively masks low-level intrusive sound from adjacent spaces without also being a source of annoyance.

Random noise is an oscillation, the instantaneous magnitude of which cannot be specified for any given instant. The instantaneous magnitudes of a random noise are specified only by probability distributions, giving the fraction of the total time that the magnitude, or some sequence of magnitudes, lies within a specified range (ANSI *Standard* S1.1). There are three types of random noise: white, pink, and red.

- **White noise** has a continuous frequency spectrum with equal energy per hertz over a specified frequency range. Because octave bands double in width for each successive band, for white noise the energy also doubles in each successive octave band. Thus white noise displayed on a 1/3 octave or octave band chart increases in level by 3 dB per octave.
- **Pink noise** has a continuous frequency spectrum with equal energy per constant-percentage bandwidth, such as per octave or 1/3 octave band. Thus pink noise appears on a 1/3 octave or octave band chart as a horizontal line.
- **Red noise** has a continuous frequency spectrum with octave band levels that decrease at a rate of 4 to 5 dB per octave with increasing frequency. Red noise is typical of noise from well-designed HVAC systems.

Predicting Human Response to Sound

Predicting the response of people to any given sound is, at best, only a statistical concept, and, at worst, very inaccurate. This is because response to sound is not only physiological but psychological and depends on the varying attitude of the listener. Hence, the effect of sound is often unpredictable. However, people respond adversely if the sound is considered too loud for the situation or if it sounds "wrong." Therefore, criteria are based on descriptors that account for level and spectrum shape.

Sound Quality

To determine the acoustic acceptability of a space to occupants, sound pressure levels in the space must be known. This, however, is often not sufficient; sound quality is important, too. Factors influencing sound quality include (1) loudness, (2) tone perception, (3) frequency balance, (4) harshness, (5) time and frequency fluctuation, and (6) vibration.

People often perceive sounds with tones (such as a whine or hum) as particularly annoying. A tone can cause a relatively low-level sound to be perceived as noise.

Loudness

The primary method for determining subjective estimations of loudness is to present sounds to a sample of listeners under controlled conditions. Listeners compare an unknown sound with a standard sound. (The accepted standard sound is a pure tone of 1000 Hz or a narrow band of random noise centered on 1000 Hz.) Loudness level is expressed in **phons**, and the loudness level of any sound in phons is equal to the sound pressure level in decibels of a standard sound deemed to be equally loud. Thus, a sound that is judged as loud as a 40 dB, 1000 Hz tone has a loudness level of 40 phons.

Average reactions of humans to tones are shown in Figure 4 (Robinson and Dadson 1956). The reaction changes when the sound is a band of random noise (Pollack 1952), rather than a pure tone (Figure 5). The figures indicate that people are most sensitive in the midfrequency range. The contours in Figure 4 are closer together at low frequencies, showing that at lower frequencies, people are less sensitive to sound level, but are more sensitive to *changes* in level.

Under carefully controlled experimental conditions, humans can detect small changes in sound level. However, for humans to describe a sound as being half or twice as loud requires changes in the overall sound pressure level of about 10 dB. For many people, a 3 dB change is the minimum perceptible difference. This means that halving the power output of the source causes a barely noticeable change in sound pressure level, and power output must be reduced by a factor of 10 before humans determine that loudness has been halved. Table 8 summarizes the effect of changes in sound levels for simple sounds in the frequency range of 250 Hz and higher.

The phon scale covers the large dynamic range of the ear, but does not fit a subjective linear loudness scale. Over most of the audible range, a doubling of loudness corresponds to a change of

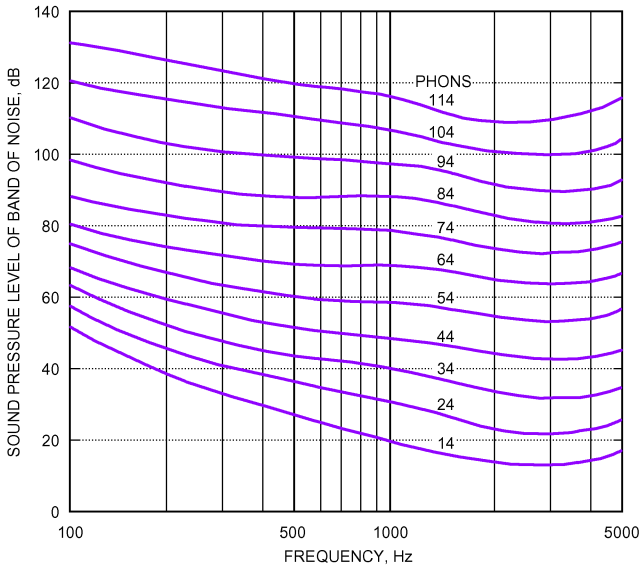

Fig. 5 Equal Loudness Contours for Relatively Narrow Bands of Random Noise

(Reprinted with permission from I. Pollack, *Journal of the Acoustical Society of America*, vol. 24, p. 533, 1952. Copyright 1952, Acoustical Society of America.)

Table 8 Subjective Effect of Changes in Sound Pressure Level, Broadband Sounds (Frequency ≥ 250 Hz)

Subjective Change	Objective Change in Sound Level (Approximate)
Much louder	More than +10 dB
Twice as loud	+10 dB
Louder	+5 dB
Just perceptibly louder	+3 dB
Just perceptibly quieter	–3 dB
Quieter	–5 dB
Half as loud	–10 dB
Much quieter	Less than –10 dB

approximately 10 phons. To obtain a quantity proportional to the loudness sensation, use a loudness scale based on the **sone**. One sone equals the loudness level of 40 phons. A rating of two sones corresponds to 50 phons, and so on. In HVAC, only the ventilation fan industry (e.g., bathroom exhaust and sidewall propeller fans) uses loudness ratings.

Standard objective methods for calculating loudness have been developed. ANSI *Standard* S3.4 calculates loudness or loudness level using 1/3 octave band sound pressure level data as a starting point. The loudness index for each 1/3 octave band is obtained from a graph or by calculation. Total loudness is then calculated by combining the loudnesses for each band according to a formula given in the standard. A graphic method using 1/3 octave band sound pressure levels to predict loudness of sound spectra containing tones is presented in Zwicker (ISO *Standard* 532) and German *Standard* DIN 45631. Because of its complexity, loudness has not been widely used in engineering practice in the past.

Acceptable Frequency Spectrum

The most acceptable frequency spectrum for HVAC sound is a balanced or neutral spectrum in which octave band levels decrease at a rate of 4 to 5 dB per octave with increasing frequency. This means that it is not too hissy (excessive high-frequency content) or too rumbly (excessive low-frequency content). Unfortunately, achieving a balanced sound spectrum is not always easy: there may be numerous sound sources to consider. As a design guide, Figure 6 shows the more common mechanical and electrical sound sources and frequency regions that control the indoor sound spectrum. Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* provides more detailed information on treating some of these sound sources.

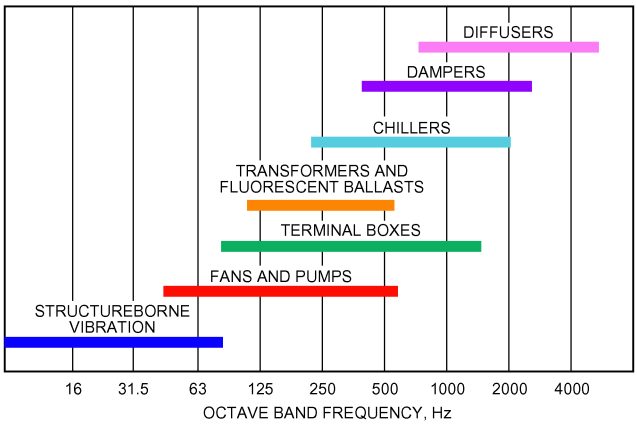

Fig. 6 Frequencies at Which Various Types of Mechanical and Electrical Equipment Generally Control Sound Spectra

11. SOUND RATING SYSTEMS AND ACOUSTICAL DESIGN GOALS

The degree of occupant satisfaction with the background noise level in any architectural space depends on the sound quality of the noise itself, the occupant's aural sensitivity, and specific task engagement. In most cases, background noise must be unobtrusive, meaning that the noise level must not be excessive enough to cause distraction or annoyance, or to interfere with, for example, music listening and speech intelligibility. In addition, the frequency content and temporal variations must not call attention to the noise intrusion, but rather present a bland and unobtrusive background. For critical listening conditions such as for music in a symphony hall or speech in grade schools, background noise must not exceed a relatively low exposure level. However, for speech and music in a high school gymnasium, a significantly higher background noise level will be tolerated. When low annoyance and distractions are a key factor, such as in open-plan offices for occupant productivity, a minimum acceptable background noise must be considered to effectively cover undesirable intruding sounds. Consequently, HVAC system sound control goals vary depending on the required use of the space.

To be unobtrusive, HVAC-related background noise should have the following properties:

- Frequency content that is broadband and smooth in nature, and at a level suitable for the use of the space
- No audible tones or other characteristics such as roar, whistle, hum, or rumble
- No significant time fluctuations in level or frequency such as throbbing or pulsing

Unfortunately, there is no standard process to easily characterize the effects of audible tones and level fluctuations, so currently available rating methods do not adequately address these issues.

Conventional approaches for rating sound in an occupied space include the following.

A-Weighted Sound Level (dBA)

The A-weighted sound level L_A is an easy-to-determine, single-number rating, expressed as a number followed by dBA (e.g.,

Licensed for single user. © 2021 ASHRAE, Inc.

40 dBA). A-weighted sound levels correlate well with human judgments of relative loudness, but do not indicate degree of spectral balance. Thus, they do not necessarily correlate well with the annoyance caused by the noise. Many different-sounding spectra can have the same numeric rating but quite different subjective qualities. A-weighted comparisons are best used with sounds that sound alike but differ in level. They should not be used to compare sounds with distinctly different spectral characteristics; two sounds at the same sound level but with different spectral content are likely to be judged differently by the listener in terms of acceptability as a background sound. One of the sounds might be completely acceptable; the other could be objectionable because its spectrum shape was rumbly, hissy, or tonal in character.

A-weighted sound levels are used extensively in outdoor environmental noise standards and for estimating the risk of damage to hearing for long-term exposures to noise, such as in industrial environments and other workplaces. In outdoor environmental noise standards, the principal sources of noise are vehicular traffic and aircraft, for which A-weighted criteria of acceptability have been developed empirically.

Outdoor HVAC equipment can create significant sound levels that affect nearby properties and buildings. Local noise ordinances often limit property line A-weighted sound levels and typically are more restrictive during nighttime hours.

Noise Criteria (NC) Method

The NC method remains the predominant design criterion used by HVAC engineers. This single-number rating is somewhat sensitive to the relative loudness and speech interference properties of a given sound spectrum. Its wide use derives in part from its ease of use and its publication in HVAC design textbooks. The method consists of a family of criterion curves now extending from 16 to 8000 Hz and a rating procedure based on speech interference levels (ANSI *Standard* S12.2-2008). The criterion curves define the limits of octave band spectra that must not be exceeded to meet acceptance in certain spaces. The NC curves shown in Figure 7 are in steps of 5 dB. NC-rating procedures for measured data use interpolation, rounded to the nearest dB.

The rating is expressed as NC followed by a number. For example, the spectrum shown is rated NC 43 because this is the lowest rating curve that falls entirely above the measured data. An NC 35 design goal is common for private offices. The background sound level meets this goal if no portion of its spectrum lies above the designated NC 35 curve.

The NC method is sensitive to level but has the disadvantage as a design criterion method that it does not require the sound spectrum to approximate the shape of the NC curves. Thus, many different sounds can have the same numeric rating, but rank differently on the basis of subjective sound quality. In many HVAC systems that do not produce excessive low-frequency sound, the NC rating correlates relatively well with occupant satisfaction if sound quality is not a significant concern or if the octave band levels have a shape similar to the nearest NC curves.

Two problems occur in using the NC procedure as a diagnostic tool. First, when the NC level is determined by a prominent peak in the spectrum, the actual level of resulting background sound may be quieter than that desired for masking unwanted speech and activity sounds, because the spectrum on either side of the tangent peak drops off too rapidly. Second, when the measured spectrum does not match the shape of the NC curve, the resulting sound might be rumbly (levels at low frequencies determine the NC rating and levels at high frequencies roll off faster than the NC curve) or hissy (the NC rating is determined by levels at high frequencies but levels at low frequencies are much less than the NC curve for the rating).

Manufacturers of terminal units and diffusers commonly use NC ratings in their published product data. Because of the numerous assumptions made to arrive at these published values (e.g., size of room, type of ceiling, number of units), relying solely on NC ratings to select terminal units and diffusers is not recommended.

Room Criterion (RC) Method

The room criterion (RC) method (ANSI *Standard* S12.2; Blazier 1981a, 1981b) is based on measured levels of HVAC noise in spaces and is used primarily as a diagnostic tool. The RC method consists of a family of criteria curves and a rating procedure. The shape of these curves differs from the NC curves to approximate a well-balanced, neutral-sounding spectrum; two additional octave bands (16 and 31.5 Hz) are added to deal with low-frequency sound, and the 8000 Hz octave band is dropped. This rating procedure assesses background sound in spaces based on its effect on speech communication, and on estimates of subjective sound quality. The rating is expressed as RC followed by a number to show the level of the sound and a letter to indicate the quality [e.g., RC 35(N), where N denotes neutral].

For a full explanation of RC curves and analysis procedures, see Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Criteria Selection Guidelines

In general, these basic guidelines are important:

- Sound levels below NC or RC 35 are generally not detrimental to good speech intelligibility. Sound levels at or above these levels may interfere with or mask speech.
- Even if the occupancy sound is significantly higher than the anticipated background sound level generated by mechanical equipment, the sound design goal should not necessarily be raised to levels approaching the occupancy sound. This avoids occupants having to raise their voices uncomfortably to be heard over the noise.

For full details and recommended background sound level criteria for different spaces, see Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications*.

12. FUNDAMENTALS OF VIBRATION

A rigidly mounted machine transmits its internal vibratory forces directly to the supporting structure. However, by inserting resilient mountings (**vibration isolators**) between the machine and supporting structure, the magnitude of transmitted force can be dramatically reduced. Vibration isolators can also be used to protect sensitive equipment from floor vibration.

Single-Degree-of-Freedom Model

The simplest representation of a vibration isolation system is the single-degree-of-freedom model, shown in Figure 8. Only motion along the vertical axis is considered. The isolated system is represented by a mass and the isolator is represented by a spring, which is considered fixed to ground. Excitation (i.e., the vibratory forces generated by the isolated equipment, such as shaft imbalance in rotating machinery) is applied to the mass. This simple model is the basis for catalog information provided by most manufacturers of vibration isolation hardware.

Mechanical Impedance

Mechanical impedance Z_m is a structural property useful in understanding the performance of vibration isolators in a given installation. Z_m is the ratio of the force F applied to the structure divided by the velocity v of the structure's vibration response at the point of excitation:

$$Z_m = F/v \tag{43}$$

At low frequencies, the mechanical impedance of a vibration isolator is approximately equal to $k/2\pi f$, where k is the stiffness of the isolator (force per unit deflection) and f is frequency in Hz (cycles per second). Note that the impedance of the isolator is inversely proportional to frequency. This characteristic is the basis for an isolator's ability to block vibration from the supported structure. In the simple single-degree-of-freedom model, impedance of the isolated mass is proportional to frequency. Thus, as frequency increases, the isolator increasingly provides an impedance mismatch between the isolated structure and ground. This mismatch attenuates the forces imposed on the ground. However, at the system's particular natural frequency (discussed in the following section), the effects of the isolator are decidedly detrimental.

Natural Frequency

Using the single-degree-of-freedom model, the frequency at which the magnitude of the spring and mass impedances are equal is the **natural frequency f_n**. At this frequency, the mass's vibration response to the applied excitation is a maximum, and the isolator actually amplifies the force transmitted to ground. The natural frequency of the system (also called the **isolation system resonance**) is given approximately by

$$f_n = \frac{1}{2\pi}\sqrt{\frac{k}{M}} \tag{44}$$

where M is the mass of the equipment supported by the isolator. The stiffness k is expressed as N/m, and M as kg.

This equation simplifies to

$$f_n = \frac{15.8}{\sqrt{\delta_{st}}} \tag{45}$$

where δ_{st} is the **isolator static deflection** (the incremental distance the isolator spring compresses under the weight of the supported equipment) in millimetres. Thus, to achieve the appropriate system natural frequency for a given application, it is customary to specify the corresponding isolator static deflection and the load to be supported at each of the mounting points.

The **transmissibility T** of this system is the ratio of the amplitudes of the force transmitted to the building structure to the exciting force produced inside the vibrating equipment. For disturbing frequency f_d, T is given by

$$T = \left| \frac{1}{1 - (f_d/f_n)^2} \right| \tag{46}$$

The transmissibility equation is plotted in Figure 9.

It is important to note that T is inversely proportional to the square of the ratio of the disturbing frequency f_d to the system natural frequency f_n. At $f_d = f_n$, resonance occurs: the denominator of Equation (46) equals zero and transmission of vibration is theoretically infinite. In practice, transmissibility at resonance is limited by damping in the system, which is always present to some degree. Thus, the magnitude of vibration amplification at resonance always has a finite, though often dramatically high, value.

Note that vibration isolation (attenuation of force applied to ground) does not occur until the ratio of the disturbing frequency f_d to the system natural frequency f_n is greater than 1.4. Above this ratio, vibration transmissibility decreases (attenuation increases) with the square of frequency.

In designing isolators, it is customary to specify a frequency ratio of at least 3.5, which corresponds to an isolation efficiency of about 90%, or 10% transmissibility. Higher ratios may be specified, but in practice this often does not greatly increase isolation efficiency,

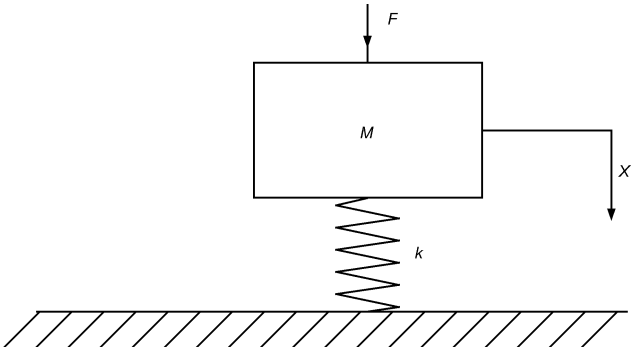

Fig. 8 Single-Degree-of-Freedom System

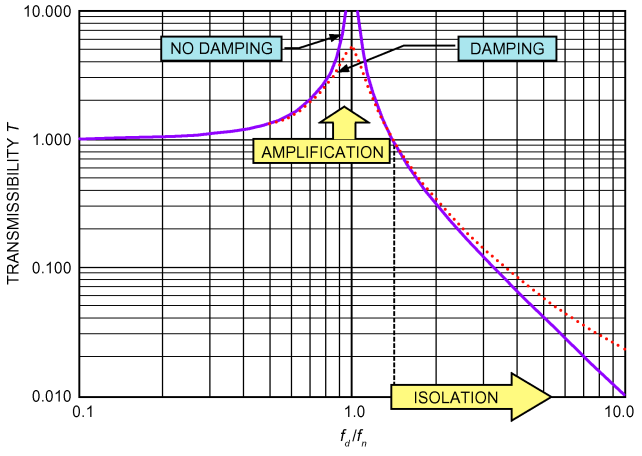

Fig. 9 Vibration Transmissibility T as Function of f_d/f_n

Licensed for single user. © 2021 ASHRAE, Inc.

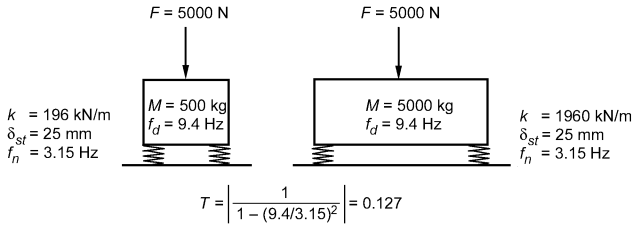

Fig. 10 Effect of Mass on Transmissibility

especially at frequencies above about 10 times the natural frequency. The reason is that wave effects and other nonlinear characteristics in real isolators cause a deviation from the theoretical curve that limits performance at higher frequencies.

To obtain the design objective of $f_d/f_n \approx 3.5$, the lowest frequency of excitation f_d is determined first. This is usually the shaft rotation rate in hertz (Hz; cycles/second). Because it is usually not possible to change the mass of the isolated equipment, the combined stiffness of the isolators is then selected such that

$$k = (2\pi f_d/3.5)^2 M \tag{47}$$

where M is the mass of the mounted equipment in kg, and k is in N/m. With four mounts, the stiffness of each mount is $k/4$, assuming equal mass distribution.

For a given set of isolators, as shown by Equations (44) and (46), if equipment mass is increased, the resonance frequency decreases and isolation increases. In practice, the load-carrying capacity of isolators usually requires that their stiffness or their number be increased. Consequently, the static deflection and transmissibility may remain unchanged.

For example, as shown in Figure 10, a 500 kg piece of equipment installed on isolators with stiffness k of 196 kN/m results in a 25 mm deflection and a system resonance frequency f_n of 3.15 Hz. If the equipment operates at 564 rpm (9.4 Hz) and develops an internal force of 5000 N, 635 N is transmitted to the structure. If the total mass is increased to 5000 kg by placing the equipment on a concrete inertia base and the stiffness of the springs is increased to 1960 kN/m, the deflection is still 25 mm, the resonance frequency of the system is maintained at 3.15 Hz, and the force transmitted to the structure remains at 635 N.

The increased mass, however, reduces equipment displacement. The forces F generated inside the mounted equipment, which do not change when mass is added to the equipment, now must excite more mass with the same internal force. Therefore, because $F = Ma$, where a is acceleration, the maximum dynamic displacement of the mounted equipment is reduced by a factor of M_1/M_2, where M_1 and M_2 are the masses before and after mass is added, respectively.

Practical Application for Nonrigid Foundations

The single-degree-of-freedom model is valid only when the impedance of the supporting structure (ground) is high relative to the impedance of the vibration isolator. This condition is usually satisfied for mechanical equipment in on-grade or basement locations. However, when heavy mechanical equipment is installed on a structural floor, particularly on the roof of a building, significantly softer vibration isolators are usually required than in the on-grade or basement case. This is because the impedance of the supporting structure can no longer be ignored.

For the two-degrees-of-freedom system in Figure 11, mass M_1 and isolator K_1 represent the supported equipment, and M_2 and K_2 represent the effective mass and stiffness of the floor structure. In

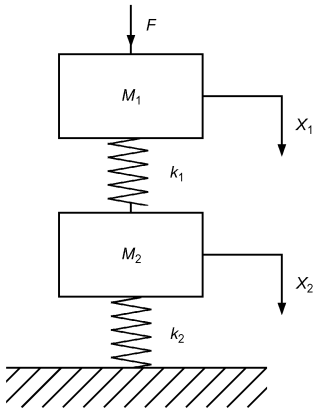

Fig. 11 Two-Degrees-of-Freedom System

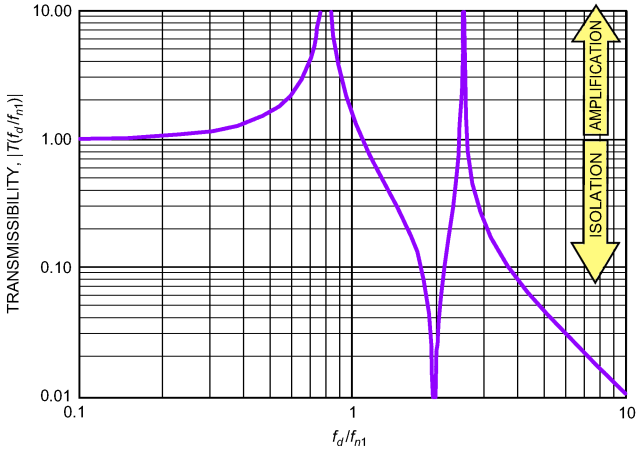

Fig. 12 Transmissibility T as Function of f_d/f_{n1} with $k_2/k_1 = 2$ and $M_2/M_1 = 0.5$

this case, transmissibility refers to the vibratory force imposed on the floor, and is given by

$$T = \frac{1}{\left[1 - \left(\frac{f_d}{f_{n1}}\right)^2\right] - \frac{1}{\left(\frac{f_{n1}}{f_d}\right)^2 \frac{k_2}{k_1} - \frac{M_2}{M_1}}} \tag{48}$$

As in Equation (46), f_d is the forcing frequency. Frequency f_{n1} is the natural frequency of the isolated equipment with a rigid foundation [Equation (44)].

The implication of Equation (48) relative to Equation (46) is that a nonrigid foundation can severely alter the effectiveness of the isolation system. Figure 12 shows transmissibility of a floor structure with twice the stiffness of the isolator, and a floor effective mass half that of the isolated equipment. Comparing Figure 12 to Figure 9 shows that the nonrigid floor introduces a second resonance well above that of the isolation system assuming a rigid floor. Unless care is taken in the isolation system design, this secondary amplification can cause a serious sound or vibration problem.

As a general rule, it is advisable to design the system such that the static deflection of the isolator, under the applied equipment weight, is on the order of 10 times the incremental static deflection of the floor caused by the equipment mass (Figure 13). Above the

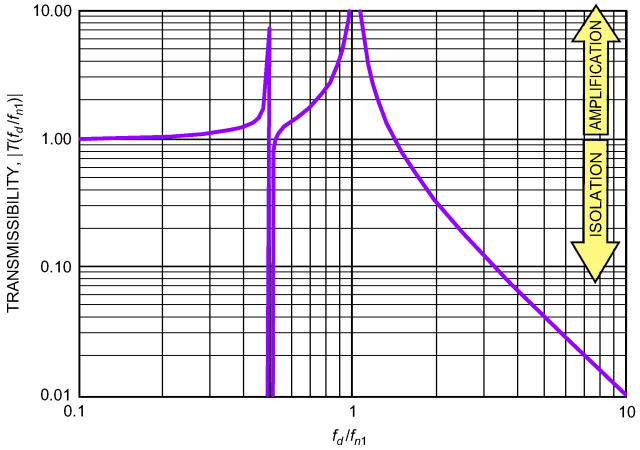

Fig. 13 Transmissibility T as Function of f_d/f_{n1} with $k_2/k_1 = 10$ and $M_2/M_1 = 40$

rigid-foundation natural frequency f_{n1}, transmissibility is comparable to that of the simple single-degree-of-freedom model.

Other complicating factors exist in actual installations, which often depart from the two-degrees-of-freedom model. These include the effects of horizontal and rotational vibration. Given these complexities, it is often beneficial to collaborate with an experienced acoustical consultant or structural engineer when designing vibration isolation systems applied to flexible floor structures.

13. VIBRATION MEASUREMENT BASICS

Control of HVAC system sound and vibration are of equal importance, but measurement of vibration is often not necessary to determine sources or transmission paths of disturbing sound.

The typical vibrations measured are periodic motions of a surface. This surface displacement oscillates at one or more frequencies produced by mechanical equipment (e.g., rotating shafts or gears), thermal processes (e.g., combustion), or fluid-dynamic means (e.g., airflow through a duct or fan interactions with air).

A **transducer** detects displacement, velocity, or acceleration of a surface and converts the motion to electrical signals. Displacement transducers are often most appropriate for low-frequency measurements. For most HVAC applications, the transducer of choice is an **accelerometer**, which is rugged and compact. The accelerometer attaches to an amplifier, which connects to a meter, much like the microphone on a sound level meter. Readouts may be in acceleration level or decibels. The measurement also specifies whether the amplitude of the acceleration sinusoid is defined by its peak, peak-to-peak, or RMS level.

For steady-state (continuous) vibration, simple relationships exist between displacement, velocity, and acceleration; output can be specified as any of these, regardless of which transducer type is used. For a given frequency f,

$$a = (2\pi f)^2 d = (2\pi f)v \tag{49}$$

where a is acceleration, v is velocity, and d is displacement.

The simplest measure is the overall signal level as a function of time. This is analogous to the unfiltered sound pressure level. If a detailed frequency analysis is needed, there is a choice of filters similar to those available for sound measurements: octave band, 1/3 octave band, or 1/12 octave band. In addition, there are narrowband analyzers that use the fast Fourier transform (FFT) to analyze and filter a signal. Though widely used, they should only be used by a specialist for accurate results.

The most important issues in vibration measurement include (1) choosing a transducer with a frequency range appropriate to the measurement, (2) properly mounting the transducer to ensure that the frequency response claimed is achieved, and (3) properly calibrating the vibration measurement system for the frequency range of interest.

For more thorough descriptions of specialized vibration measurement and analysis methods, designers should consult other sources [e.g., Harris (1991)].

14. SYMBOLS

A = magnitude of physical property [Equation (1)], surface area, m^2
a = acceleration, m/s^2
c = speed of sound in air, 335 m/s
d = distance of measurement from nearest reflecting surface, or displacement, m
d_f = deflection of foundation
d_I = deflection of mounts
E = Young's modulus, N/m^2
F = force applied to structure, N
f = frequency, Hz
f_c = critical frequency, Hz
f_d = disturbing frequency, Hz
f_n = system natural frequency, Hz
f_r = rotation speed of fan blades, rev/s
h = thickness of outer panel of partition, mm
I = sound intensity, dB
I_{ave} = time-averaged sound intensity
k = stiffness of vibration isolator, N/m
L = level of magnitude of sound or vibration
L_{eq} = equivalent continuous sound pressure level
L_I = level of sound intensity
L_p = sound pressure level, dB
L_w = sound power level
M = mass of equipment supported by isolator, kg
M_1 = mass of equipment before additional mass added, kg
M_2 = mass of equipment after additional mass added, kg
N = number of fan blades
p = acoustic pressure
Q = directivity factor, dimensionless
R = room constant
r = distance between site of measurement and nondirectional sound source, m
Re = real part of complex quantity
S = surface area, m^2
t or T = time, s
T = system transmissibility
T_{60} = reverberation time
V = volume of room, m^3
v = velocity
v_b = velocity of flow over fan blade, m/s
v_0 = free stream velocity of flow into fan, m/s
W = total sound power
w = sound power of source, W
W_0 = input power
W_M = output power
w_s = surface mass of panel, kg/m^2
W_{SG} = power of self-noise
x = location of measurement of pressure p, Equation (17)
z_a = acoustic impedance, $kg/(m^2 \cdot s)$ or $(N \cdot s)/m^3$
Z_f = impedance of foundation where isolator attached, $(N \cdot s)/m$
Z_I = isolator impedance, $(N \cdot s)/m$
Z_m = mechanical impedance of structure, $(N \cdot s)/m$

Greek

α = absorption coefficient
$\bar{\alpha}$ = average absorption coefficient of room surface at given frequency
δ_{st} = isolator static deflection, mm
θ = direction
λ = wavelength, m
ρ = density, kg/m^3

Licensed for single user. © 2021 ASHRAE, Inc.

Subscripts

0 = maximum amplitude
abs = absorbed
ave = average
i = value for *i*th source
inc = incident
ref = reference magnitude of physical property [Equation (1)]
w = sound power

Special Environments 9.23
Symbols 9.28

A principal purpose of HVAC is to provide conditions for human thermal comfort, "that condition of mind that expresses satisfaction with the thermal environment and is assessed by subjective evaluation" (ASHRAE *Standard* 55). This definition leaves open what is meant by "condition of mind" or "satisfaction," but it correctly emphasizes that judgment of comfort is a cognitive process involving many inputs influenced by physical, physiological, psychological, and other processes. This chapter summarizes the fundamentals of human thermoregulation and comfort in terms useful to the engineer for operating systems and designing for the comfort and health of building occupants.

The conscious mind appears to reach conclusions about thermal comfort and discomfort from direct temperature and moisture sensations from the skin, deep body temperatures, and the efforts necessary to regulate body temperatures (Berglund 1995; Gagge 1937; Hardy et al. 1971; Hensel 1973, 1981). In general, comfort occurs when body temperatures are held within narrow ranges, skin moisture is low, and the physiological effort of regulation is minimized.

Comfort also depends on behaviors that are initiated consciously or unconsciously and guided by thermal and moisture sensations to reduce discomfort. Some examples are altering clothing, altering activity, changing posture or location, changing the thermostat setting, opening a window, complaining, or leaving the space.

Surprisingly, although climates, living conditions, and cultures differ widely throughout the world, the temperature that people choose for comfort under similar conditions of clothing, activity, humidity, and air movement has been found to be very similar (Busch 1992; de Dear et al. 1991; Fanger 1972).

1. HUMAN THERMOREGULATION

Metabolic activities of the body result almost completely in heat that must be continuously dissipated and regulated to maintain normal body temperatures. Insufficient heat loss leads to overheating (**hyperthermia**), and excessive heat loss results in body cooling (**hypothermia**). Skin temperature greater than 45°C or less than 18°C causes pain (Hardy et al. 1952). Skin temperatures associated with comfort at sedentary activities are 33 to 34°C and decrease with increasing activity (Fanger 1967). In contrast, internal temperatures rise with activity. The temperature regulatory center in the brain is about 36.8°C at rest in comfort and increases to about 37.4°C when walking and 37.9°C when jogging. An internal temperature less than about 28°C can lead to serious cardiac arrhythmia and death, and a temperature greater than 43°C can cause irreversible brain damage. Therefore, careful regulation of body temperature is critical to comfort and health.

A resting adult produces about 100 W of heat. Because most of this is transferred to the environment through the skin, it is often convenient to characterize metabolic activity in terms of heat production per unit area of skin. For a resting person, this is about 58 W/m^2 and is called 1 **met**. This is based on the average male European, with a skin surface area of about 1.8 m^2. For comparison, female Europeans have an average surface area of 1.6 m^2. Systematic differences in this parameter may occur between ethnic and geographical groups. Higher metabolic rates are often described in terms of the resting rate. Thus, a person working at metabolic rate five times the resting rate would have a metabolic rate of 5 met.

The **hypothalamus**, located in the brain, is the central control organ for body temperature. It has hot and cold temperature sensors and is bathed by arterial blood. Because the recirculation rate of blood is rapid and returning blood is mixed together in the heart before returning to the body, arterial blood is indicative of the average internal body temperature. The hypothalamus also receives thermal information from temperature sensors in the skin and perhaps other locations as well (e.g., spinal cord, gut), as summarized by Hensel (1981).

The hypothalamus controls various physiological processes to regulate body temperature. Its control behavior is primarily proportional to deviations from set-point temperatures with some integral and derivative response aspects. The most important and often-used physiological process is regulating blood flow to the skin: when internal temperatures rise above a set point, more blood is directed to the skin. This **vasodilation** of skin blood vessels can increase skin blood flow by 15 times [from 1.7 mL/(s·m^2) at resting comfort to 25 mL/(s·m^2)] in extreme heat to carry internal heat to the skin for transfer to the environment. When body temperatures fall below the set point, skin blood flow is reduced (**vasoconstricted**) to conserve heat. The effect of maximum vasoconstriction is equivalent to the insulating effect of a heavy sweater. At temperatures less than the set point, muscle tension increases to generate additional heat; where muscle groups are opposed, this may increase to visible shivering, which can increase resting heat production to 4.5 met.

At elevated internal temperatures, sweating occurs. This defense mechanism is a powerful way to cool the skin and increase heat loss from the core. The sweating function of the skin and its control is more advanced in humans than in other animals and is increasingly necessary for comfort at metabolic rates above resting level (Fanger 1967). Sweat glands pump perspiration onto the skin surface for evaporation. If conditions are good for evaporation, the skin can remain relatively dry even at high sweat rates with little perception of sweating. At skin conditions less favorable for evaporation, the sweat must spread on the skin around the sweat gland until the sweat-covered area is sufficient to evaporate the sweat coming to the surface. The fraction of the skin that is covered with water to account for the observed total evaporation rate is termed **skin wettedness** (Gagge 1937).

Humans are quite good at sensing skin moisture from perspiration (Berglund 1994; Berglund and Cunningham 1986), and skin moisture correlates well with warm discomfort and unpleasantness (Winslow et al. 1937). It is rare for a sedentary or slightly active person to be comfortable with a skin wettedness greater than 25%. In addition to

The preparation of this chapter is assigned to TC 2.1, Physiology and Human Environment.

the perception of skin moisture, skin wettedness increases the friction between skin and fabrics, making clothing feel less pleasant and fabrics feel more coarse (Gwosdow et al. 1986). This also occurs with architectural materials and surfaces, particularly smooth, nonhygroscopic surfaces.

With repeated intermittent heat exposure, the set point for the onset of sweating decreases and the proportional gain or temperature sensitivity of the sweating system increases (Gonzalez et al. 1978; Hensel 1981). However, under long-term exposure to hot conditions, the set point increases, perhaps to reduce the physiological effort of sweating. Perspiration, as secreted, has a lower salt concentration than interstitial body fluid or blood plasma. After prolonged heat exposure, sweat glands further reduce the salt concentration of sweat to conserve salt.

At the skin's surface, the water in sweat evaporates while the dissolved salt and other constituents remain and accumulate. Because salt lowers the vapor pressure of water and thereby impedes its evaporation, the accumulating salt results in increased skin wettedness. Some of the relief and pleasure of washing after a warm day is related to the restoration of a hypotonic sweat film and decreased skin wettedness. Other adaptations to heat are increased blood flow and sweating in peripheral regions where heat transfer is better. Such adaptations are examples of **integral control**.

Role of Thermoregulatory Effort in Comfort. Chatonnet and Cabanac (1965) compared the sensation of placing a subject's hand in relatively hot or cold water (30 to 38°C) for 30 s with the subject at different thermal states. When the person was overheated (hyperthermic), the cold water was pleasant and the hot water was very unpleasant, but when the subject was cold (hypothermic), the hand felt pleasant in hot water and unpleasant in cold water. Kuno (1995) describes similar observations during transient whole-body exposures to hot and cold environment. When a subject is in a state of thermal discomfort, any move away from the thermal stress of the uncomfortable environment is perceived as pleasant during the transition.

2. ENERGY BALANCE

Figure 1 shows the thermal interaction of the human body with its environment. The total metabolic rate M within the body is the metabolic rate required for the person's activity M_{act} plus the metabolic level required for shivering M_{shiv} (should shivering occur). Some of the body's energy production may be expended as external work W; the net heat production $M - W$ is transferred to the environment through the skin surface (q_{sk}) and respiratory tract (q_{res}) with any surplus or deficit stored (S), causing the body's temperature to rise or fall.

$$M - W = q_{sk} + q_{res} + S$$
$$= (C + R + E_{sk}) + (C_{res} + E_{res}) + (S_{sk} + S_{cr}) \quad (1)$$

where

M = rate of metabolic heat production, W/m²
W = rate of mechanical work accomplished, W/m²
q_{sk} = total rate of heat loss from skin, W/m²
q_{res} = total rate of heat loss through respiration, W/m²
$C + R$ = sensible heat loss from skin, W/m²
E_{sk} = total rate of evaporative heat loss from skin, W/m²
C_{res} = rate of convective heat loss from respiration, W/m²
E_{res} = rate of evaporative heat loss from respiration, W/m²
S_{sk} = rate of heat storage in skin compartment, W/m²
S_{cr} = rate of heat storage in core compartment, W/m²

Heat dissipates from the body to the immediate surroundings by several modes of heat exchange: sensible heat flow $C + R$ from the skin; latent heat flow from sweat evaporation E_{rsw} and from evaporation of moisture diffused through the skin E_{dif}; sensible heat flow during respiration C_{res}; and latent heat flow from evaporation of moisture during respiration E_{res}. Sensible heat flow from the skin may be a complex mixture of conduction, convection, and radiation for a clothed person; however, it is equal to the sum of the convection C and radiation R heat transfer at the outer clothing surface (or exposed skin).

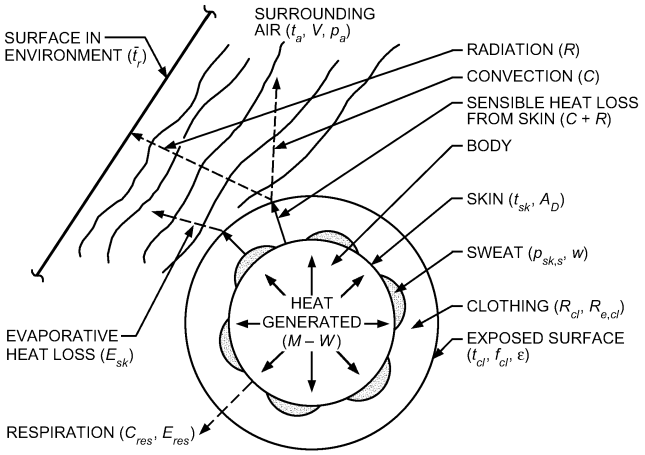

Fig. 1 Thermal Interaction of Human Body and Environment

Sensible and latent heat losses from the skin are typically expressed in terms of environmental factors, skin temperature t_{sk}, and skin wettedness w. Factors also account for thermal insulation and moisture permeability of clothing. The independent environmental variables can be summarized as air temperature t_a, mean radiant temperature $\bar{t}_r$, relative air velocity V, and ambient water vapor pressure p_a. The independent personal variables that influence thermal comfort are activity and clothing.

The rate of heat storage in the body equals the rate of increase in internal energy. The body can be considered as two thermal compartments: the skin and the core (see the Two-Node Model section under Prediction of Thermal Comfort). The storage rate can be written separately for each compartment in terms of thermal capacity and time rate of change of temperature in each compartment:

$$S_{cr} = \frac{(1 - \alpha_{sk}) m c_{p,b}}{A_D} \times \frac{dt_{cr}}{d\theta} \quad (2)$$

$$S_{sk} = \frac{\alpha_{sk} m c_{p,b}}{A_D} \times \frac{dt_{sk}}{d\theta} \quad (3)$$

where

α_{sk} = fraction of body mass concentrated in skin compartment
m = body mass, kg
$c_{p,b}$ = specific heat capacity of body = 3490 J/(kg·K)
A_D = DuBois surface area, m²
t_{cr} = temperature of core compartment, °C
t_{sk} = temperature of skin compartment, °C
θ = time, s

The fractional skin mass α_{sk} depends on the rate $\dot{m}_{bl}$ of blood flowing to the skin surface.

3. THERMAL EXCHANGES WITH ENVIRONMENT

Fanger (1967, 1970), Gagge and Hardy (1967), Hardy (1949), and Rapp and Gagge (1967) give quantitative information on calculating heat exchange between people and the environment. This section summarizes the mathematical statements for various terms of heat exchange used in the heat balance equations (C, R, E_{sk}, C_{res}, E_{res}). Terms describing the heat exchanges associated with the

Licensed for single user. © 2021 ASHRAE, Inc.

thermoregulatory control mechanisms ($q_{cr,sk}$, M_{shiv}, E_{rsw}), values for the coefficients, and appropriate equations for M_{act} and A_D are presented in later sections.

Mathematical description of the energy balance of the human body combines rational and empirical approaches to describing thermal exchanges with the environment. Fundamental heat transfer theory is used to describe the various mechanisms of sensible and latent heat exchange, and empirical expressions are used to determine the values of coefficients describing these rates of heat exchange. Empirical equations are also used to describe the thermophysiological control mechanisms as a function of skin and core temperatures in the body.

Body Surface Area

The terms in Equation (1) have units of power per unit area and refer to the surface area of the nude body. The most useful measure of nude body surface area, originally proposed by DuBois and DuBois (1916), is described by

$$A_D = 0.202 m^{0.425} l^{0.725} \tag{4}$$

where

A_D = DuBois surface area, m^2
m = mass, kg
l = height, m

A correction factor $f_{cl} = A_{cl}/A_D$ must be applied to the heat transfer terms from the skin (C, R, and E_{sk}) to account for the actual surface area A_{cl} of the clothed body. Table 7 presents f_{cl} values for various clothing ensembles. For a 1.73 m tall, 70 kg man, $A_D = 1.8$ m^2. All terms in the basic heat balance equations are expressed per unit DuBois surface area.

Sensible Heat Loss from Skin

Sensible heat exchange from the skin must pass through clothing to the surrounding environment. These paths are treated in series and can be described in terms of heat transfer (1) from the skin surface, through the clothing insulation, to the outer clothing surface, and (2) from the outer clothing surface to the environment.

Both convective C and radiative R heat losses from the outer surface of a clothed body can be expressed in terms of a heat transfer coefficient and the difference between the mean temperature t_{cl} of the outer surface of the clothed body and the appropriate environmental temperature:

$$C = f_{cl} h_c (t_{cl} - t_a) \tag{5}$$

$$R = f_{cl} h_r (t_{cl} - \bar{t}_r) \tag{6}$$

where

h_c = convective heat transfer coefficient, $W/(m^2 \cdot K)$
h_r = linear radiative heat transfer coefficient, $W/(m^2 \cdot K)$
f_{cl} = clothing area factor A_{cl}/A_D, dimensionless

The coefficients h_c and h_r are both evaluated at the clothing surface. Equations (5) and (6) are commonly combined to describe the total sensible heat exchange by these two mechanisms in terms of an operative temperature t_o and a combined heat transfer coefficient h:

$$C + R = f_{cl} h (t_{cl} - t_o) \tag{7}$$

where

$$t_o = \frac{h_r \bar{t}_r + h_c t_a}{h_r + h_c} \tag{8}$$

$$h = h_r + h_c \tag{9}$$

Based on Equation (8), operative temperature t_o can be defined as the average of the mean radiant and ambient air temperatures, weighted by their respective heat transfer coefficients.

The actual transport of sensible heat through clothing involves conduction, convection, and radiation. It is usually most convenient to combine these into a single thermal resistance value R_{cl}, defined by

$$C + R = (t_{sk} - t_{cl})/R_{cl} \tag{10}$$

where R_{cl} is the thermal resistance of clothing in $(m^2 \cdot K)/W$.

Because it is often inconvenient to include the clothing surface temperature in calculations, Equations (7) and (10) can be combined to eliminate t_{cl}:

$$C + R = \frac{t_{sk} - t_o}{R_{cl} + 1/(f_{cl} h)} \tag{11}$$

where t_o is defined in Equation (8).

Evaporative Heat Loss from Skin

Evaporative heat loss E_{sk} from skin depends on the amount of moisture on the skin and the difference between the water vapor pressure at the skin and in the ambient environment:

$$E_{sk} = \frac{w(p_{sk,s} - p_a)}{R_{e,cl} + 1/(f_{cl} h_e)} \tag{12}$$

where

w = skin wettedness, dimensionless
$p_{sk,s}$ = water vapor pressure at skin, normally assumed to be that of saturated water vapor at t_{sk}, kPa
p_a = water vapor pressure in ambient air, kPa
$R_{e,cl}$ = evaporative heat transfer resistance of clothing layer (analogous to R_{cl}), $(m^2 \cdot kPa)/W$
h_e = evaporative heat transfer coefficient (analogous to h_c), $W/(m^2 \cdot kPa)$

Procedures for calculating $R_{e,cl}$ and h_e are given in the section on Engineering Data and Measurements. Skin wettedness is the ratio of the actual evaporative heat loss E_{sk} to the maximum possible evaporative heat loss E_{max} with the same conditions and a completely wet skin ($w = 1$). Skin wettedness is important in determining evaporative heat loss. Maximum evaporative potential E_{max} occurs when $w = 1$.

Evaporative heat loss from the skin is a combination of the evaporation of sweat secreted because of thermoregulatory control mechanisms E_{rsw} and the natural diffusion of water through the skin E_{dif}:

$$E_{sk} = E_{rsw} + E_{dif} \tag{13}$$

Evaporative heat loss by regulatory sweating is directly proportional to the rate of regulatory sweat generation:

$$E_{rsw} = \dot{m}_{rsw} h_{fg} \tag{14}$$

where

h_{fg} = heat of vaporization of water = 2.43×10^6 J/kg at 30°C
$\dot{m}_{rsw}$ = rate at which regulatory sweat is generated, $kg/(s \cdot m^2)$

The portion w_{rsw} of a body that must be wetted to evaporate the regulatory sweat is

$$w_{rsw} = E_{rsw}/E_{max} \tag{15}$$

With no regulatory sweating, skin wettedness caused by diffusion is approximately 0.06 for normal conditions. For large values of E_{max} or long exposures to low humidities, the value may drop to as low as 0.02, because dehydration of the outer skin layers alters its diffusive

Licensed for single user. © 2021 ASHRAE, Inc.

characteristics. With regulatory sweating, the 0.06 value applies only to the portion of skin not covered with sweat $(1 - w_{rsw})$; the diffusion evaporative heat loss is

$$E_{dif} = (1 - w_{rsw})0.06E_{max} \quad (16)$$

These equations can be solved for w, given the maximum evaporative potential E_{max} and the regulatory sweat generation E_{rsw}:

$$w = w_{rsw} + 0.06(1 - w_{rsw}) = 0.06 + 0.94E_{rsw}/E_{max} \quad (17)$$

Once skin wettedness is determined, evaporative heat loss from the skin is calculated from Equation (12), or by

$$E_{sk} = wE_{max} \quad (18)$$

To summarize, the following calculations determine w and E_{sk}:

E_{max}	Equation (12), with $w = 1.0$
E_{rsw}	Equation (14)
w	Equation (17)
E_{sk}	Equation (18) or (12)

Although evaporation from the skin E_{sk} as described in Equation (12) depends on w, the body does not directly regulate skin wettedness but, rather, regulates sweat rate m_{rsw} [Equation (14)]. Skin wettedness is then an indirect result of the relative activity of the sweat glands and the evaporative potential of the environment. Skin wettedness of 1.0 is the upper theoretical limit. If the aforementioned calculations yield a wettedness of more than 1.0, then Equation (14) is no longer valid because not all the sweat is evaporated. In this case, $E_{sk} = E_{max}$.

Skin wettedness is strongly correlated with warm discomfort and is also a good measure of thermal stress. Theoretically, skin wettedness can approach 1.0 while the body still maintains thermoregulatory control. In most situations, it is difficult to exceed 0.8 (Berglund and Gonzalez 1977). Azer (1982) recommends 0.5 as a practical upper limit for sustained activity for a healthy, acclimatized person.

Respiratory Losses

During respiration, the body loses both sensible and latent heat by convection and evaporation of heat and water vapor from the respiratory tract to the inhaled air. A significant amount of heat can be associated with respiration because air is inspired at ambient conditions and expired nearly saturated at a temperature only slightly cooler than t_{cr}.

The total heat and moisture losses through respiration are

$$q_{res} = C_{res} + E_{res} = \frac{m_{res}(h_{ex} - h_a)}{A_D} \quad (19)$$

$$m_{w,res} = \frac{m_{res}(W_{ex} - W_a)}{A_D} \quad (20)$$

where

m_{res} = pulmonary ventilation rate, kg/s
h_{ex} = enthalpy of exhaled air, J/kg (dry air)
h_a = enthalpy of inspired (ambient) air, J/kg (dry air)
$m_{w,res}$ = pulmonary water loss rate, kg/s
W_{ex} = humidity ratio of exhaled air, kg (water vapor)/kg (dry air)
W_a = humidity ratio of inspired (ambient) air, kg (water vapor)/kg (dry air)

Under normal circumstances, pulmonary ventilation rate is primarily a function of metabolic rate (Fanger 1970):

$$m_{res} = K_{res}MA_D \quad (21)$$

where

M = metabolic rate, W/m^2
K_{res} = proportionality constant 1.43×10^{-6} kg/J

For typical indoor environments (McCutchan and Taylor 1951), the exhaled temperature and humidity ratio are given in terms of ambient conditions:

$$t_{ex} = 32.6 + 0.066t_a + 32W_a \quad (22)$$

$$W_{ex} = 0.0277 + 0.000065t_a + 0.2W_a \quad (23)$$

where ambient t_a and exhaled t_{ex} air temperatures are in °C. For extreme conditions, such as outdoor winter environments, different relationships may be required (Holmér 1984).

The humidity ratio of ambient air can be expressed in terms of total or barometric pressure p_t and ambient water vapor pressure p_a:

$$W_a = \frac{0.622p_a}{p_t - p_a} \quad (24)$$

Respiratory heat loss is often expressed in terms of sensible C_{res} and latent E_{res} heat losses. Two approximations are commonly used to simplify Equations (22) and (23) for that purpose. First, because dry respiratory heat loss is relatively small compared to the other terms in the heat balance, an average value for t_{ex} is determined by evaluating Equation (22) at standard conditions of 20°C, 50% rh, sea level. Second, noting in Equation (23) that there is only a weak dependence on t_a, the second term in Equation (23) and the denominator in Equation (24) are evaluated at standard conditions. Using these approximations and substituting latent heat h_{fg} and specific heat of air $c_{p,a}$ at standard conditions, C_{res} and E_{res} can be determined by

$$C_{res} = 0.0014M(34 - t_a) \quad (25)$$

$$E_{res} = 0.0173M(5.87 - p_a) \quad (26)$$

where p_a is expressed in kPa and t_a is in °C.

Alternative Formulations

Equations (11) and (12) describe heat loss from skin for clothed people in terms of clothing parameters R_{cl}, $R_{e,cl}$, and f_{cl}; parameters h and h_e describe outer surface resistances. Other parameters and definitions are also used. Although these alternative parameters and definitions may be confusing, note that information presented in one form can be converted to another form. Table 1 presents common parameters and their qualitative descriptions. Table 2 presents equations showing their relationship to each other. Generally, parameters related to dry or evaporative heat flows are not independent because they both rely, in part, on the same physical processes. The **Lewis relation** describes the relationship between convective heat transfer and mass transfer coefficients for a surface [see Equation (41) in Chapter 6]. The Lewis relation can be used to relate convective and evaporative heat transfer coefficients defined in Equations (5) and (12) according to

$$\text{LR} = h_e/h_c \quad (27)$$

where LR is the **Lewis ratio** and, at typical indoor conditions, equals approximately 16.5 K/kPa. The Lewis relation applies to surface convection coefficients. Heat transfer coefficients that include the effects of insulation layers and/or radiation are still coupled, but the relationship may deviate significantly from that for a surface. The *i* terms in Tables 1 and 2 describe how the actual ratios of these parameters deviate from the ideal Lewis ratio (Oohori et al. 1984; Woodcock 1962).

Table 1 Parameters Used to Describe Clothing

Sensible Heat Flow

R_{cl} = intrinsic clothing insulation: thermal resistance of a uniform layer of insulation covering entire body that has same effect on sensible heat flow as actual clothing.

R_t = total insulation: total equivalent uniform thermal resistance between body and environment: clothing and boundary resistance.

R_{cle} = effective clothing insulation: increased body insulation due to clothing as compared to nude state.

R_a = boundary insulation: thermal resistance at skin boundary for nude body.

$R_{a,cl}$ = outer boundary insulation: thermal resistance at outer boundary (skin or clothing).

R_{te} = total effective insulation.

h' = overall sensible heat transfer coefficient: overall equivalent uniform conductance between body (including clothing) and environment.

h'_{cl} = clothing conductance: thermal conductance of uniform layer of insulation covering entire body that has same effect on sensible heat flow as actual clothing.

F_{cle} = effective clothing thermal efficiency: ratio of actual sensible heat loss to that of nude body at same conditions.

F_{cl} = intrinsic clothing thermal efficiency: ratio of actual sensible heat loss to that of nude body at same conditions including adjustment for increase in surface area due to clothing.

Evaporative Heat Flow

$R_{e,cl}$ = evaporative heat transfer resistance of clothing: impedance to transport of water vapor of uniform layer of insulation covering entire body that has same effect on evaporative heat flow as actual clothing.

$R_{e,t}$ = total evaporative resistance: total equivalent uniform impedance to transport of water vapor from skin to environment.

F_{pcl} = permeation efficiency: ratio of actual evaporative heat loss to that of nude body at same conditions, including adjustment for increase in surface area due to clothing.

Parameters Relating Sensible and Evaporative Heat Flows

i_{cl} = clothing vapor permeation efficiency: ratio of actual evaporative heat flow capability through clothing to sensible heat flow capability as compared to Lewis ratio.

i_m = total vapor permeation efficiency: ratio of actual evaporative heat flow capability between skin and environment to sensible heat flow capability as compared to Lewis ratio.

i_a = air layer vapor permeation efficiency: ratio of actual evaporative heat flow capability through outer air layer to sensible heat flow capability as compared to Lewis ratio.

Table 2 Relationships Between Clothing Parameters

Sensible Heat Flow

$$R_t = R_{cl} + 1/(hf_{cl}) = R_{cl} + R_a/f_{cl}$$
$$R_{te} = R_{cle} + 1/h = R_{cle} + R_a$$
$$h'_{cl} = 1/R_{cl}$$
$$h' = 1/R_t$$
$$h = 1/R_a$$
$$R_{a,cl} = R_a/f_{cl}$$
$$F_{cl} = h'/(hf_{cl}) = 1/(1 + f_{cl}hR_{cl})$$
$$F_{cle} = h'/h = f_{cl}/(1 + f_{cl}hR_{cl}) = f_{cl}F_{cl}$$

Evaporative Heat Flow

$$R_{e,t} = R_{e,cl} + 1/(h_e f_{cl}) = R_{e,cl} + R_{e,a}/f_{cl}$$
$$h_e = 1/R_{e,a}$$
$$h'_{e,cl} = 1/R_{e,cl}$$
$$h'_e = 1/R_{e,t} = f_{cl}F_{pcl}h_e$$
$$F_{pcl} = 1/(1 + f_{cl}h_eR_{e,cl})$$

Parameters Relating Sensible and Evaporative Heat Flows

$$i_{cl}\mathrm{LR} = h'_{e,cl}/h'_{cl} = R_{cl}/R_{e,cl}$$
$$i_m\mathrm{LR} = h'_e/h' = R_t/R_{e,t}$$
$$i_m = (R_{cl} + R_{a,cl})/[(R_{cl}/i_{cl}) + (R_{a,cl}/i_a)]$$
$$i_a\mathrm{LR} = h_e/h$$
$$i_a = h_c/(h_c + h_r)$$

Table 3 Skin Heat Loss Equations

Sensible Heat Loss

$$C + R = (t_{sk} - t_o)/[R_{cl} + 1/(f_{cl}h)]$$
$$C + R = (t_{sk} - t_o)/R_t$$
$$C + R = F_{cle}h(t_{sk} - t_o)$$
$$C + R = F_{cl}f_{cl}h(t_{sk} - t_o)$$
$$C + R = h'(t_{sk} - t_o)$$

Evaporative Heat Loss

$$E_{sk} = w(p_{sk,s} - p_a)/[R_{e,cl} + 1/(f_{cl}h_e)]$$
$$E_{sk} = w(p_{sk,s} - p_a)/R_{e,t}$$
$$E_{sk} = wF_{pcl}f_{cl}h_e(p_{sk,s} - p_a)$$
$$E_{sk} = h'_e w(p_{sk,s} - p_a)$$
$$E_{sk} = h' wi_m\mathrm{LR}(p_{sk,s} - p_a)$$

Depending on the combination of parameters used, heat transfer from the skin can be calculated using several different formulations (see Tables 2 and 3). If the parameters are used correctly, the end result will be the same regardless of the formulation used.

Total Skin Heat Loss

Total skin heat loss (sensible heat plus evaporative heat) can be calculated from any combination of the equations presented in Table 3. Total skin heat loss is used as a measure of the thermal environment; two combinations of parameters that yield the same total heat loss for a given set of body conditions (t_{sk} and w) are considered to be approximately equivalent. The fully expanded skin heat loss equation, showing each parameter that must be known or specified, is as follows:

$$q_{sk} = \frac{t_{sk} - t_o}{R_{cl} + R_{a,cl}} + \frac{w(p_{sk,s} - p_a)}{R_{e,cl} + 1/(\mathrm{LR}h_c f_{cl})} \tag{28}$$

where t_o is the operative temperature and represents the temperature of a uniform environment ($t_a - \bar{t}_r$) that transfers dry heat at the same rate as in the actual environment [$t_o = (\bar{t}_r h_r + t_a h_c)/(h_c + h_r)$]. After rearranging, Equation (28) becomes

$$q_{sk} = F_{cl}f_{cl}h(t_{sk} - t_o) + w\mathrm{LR}F_{pcl}h_c(p_{sk,s} - p_a) \tag{29}$$

This equation allows evaluation of the trade-off between any two or more parameters under given conditions. If the trade-off between two specific variables (e.g., operative temperature and humidity) is to be examined, then a simplified form of the equation suffices (Fobelets and Gagge 1988):

$$q_{sk} = h'[(t_{sk} + wi_m\mathrm{LR}p_{sk,s}) - (t_o + wi_m\mathrm{LR}p_a)] \tag{30}$$

Equation (30) can be used to define a combined temperature t_{com}, which reflects the combined effect of operative temperature and humidity for an actual environment:

$$t_{com} + wi_m\mathrm{LR}p_{tcom} = t_o + wi_m\mathrm{LR}p_a$$

or

$$t_{com} = t_o + wi_m\mathrm{LR}p_a - wi_m\mathrm{LR}p_{tcom} \tag{31}$$

Licensed for single user. © 2021 ASHRAE, Inc.

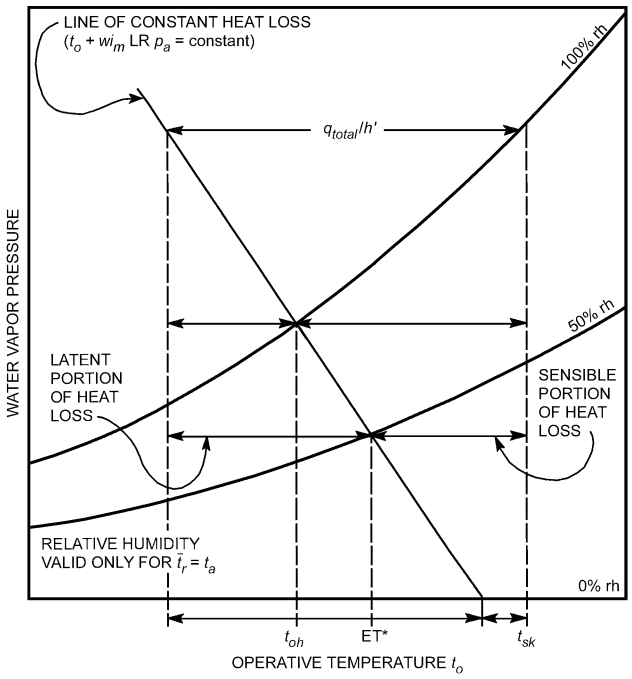

Fig. 2 Constant Skin Heat Loss Line and Its Relationship to t_{oh} and ET*

where p_{tcom} is a vapor pressure related in some fixed way to t_{com} and is analogous to $p_{wb,s}$ for t_{wb}. The term wi_mLRp_{tcom} is constant to the extent that i_m is constant, and any combination of t_o and p_a that gives the same t_{com} results in the same total heat loss.

Two important environmental indices, humid operative temperature t_{oh} and effective temperature ET*, can be represented in terms of Equation (31). The humid operative temperature is that temperature which at 100% rh yields the same total heat loss as for the actual environment:

$$t_{oh} = t_o + wi_m\text{LR}(p_a - p_{oh,s}) \tag{32}$$

where $p_{oh,s}$ is saturated vapor pressure, in kPa, at t_{oh}.

The effective temperature is the temperature at 50% rh that yields the same total heat loss from the skin as for the actual environment:

$$\text{ET*} = t_o + wi_m\text{LR}(p_a - 0.5p_{\text{ET*},s}) \tag{33}$$

where $p_{\text{ET*},s}$ is saturated vapor pressure, in kPa, at ET*.

The psychrometric chart in Figure 2 shows a constant total heat loss line and the relationship between these indices. This line represents only one specific skin wettedness and permeation efficiency index. The relationship between indices depends on these two parameters (see the section on Environmental Indices).

4. ENGINEERING DATA AND MEASUREMENTS

Applying basic equations to practical problems of the thermal environment requires quantitative estimates of the body's surface area, metabolic requirements for a given activity and the mechanical efficiency for the work accomplished, evaluation of heat transfer coefficients h_r and h_c, and the general nature of clothing insulation used. This section provides the necessary data and describes how to measure the parameters of the heat balance equation.

Metabolic Rate and Mechanical Efficiency

Maximum Capacity. In choosing optimal conditions for comfort and health, the rate of work done during routine physical activities must be known, because metabolic power increases in proportion to exercise intensity. Metabolic rate varies over a wide range, depending on the activity, person, and conditions under which the activity is performed. Table 4 lists typical metabolic rates for an average adult (A_D = 1.8 m^2) for activities performed continuously. The highest power a person can maintain for any continuous period is approximately 50% of the maximal capacity to use oxygen (maximum energy capacity).

Table 4 Typical Metabolic Heat Generation for Various Activities

	W/m^2	met*
Resting		
Sleeping	40	0.7
Reclining	45	0.8
Seated, quiet	60	1.0

*1 met = 58.1 W/m^2

A unit used to express the metabolic rate per unit DuBois area is the **met**, defined as the metabolic rate of a sedentary person (seated, quiet): 1 met = 58.1 W/m^2 = 50 kcal/(h·m^2). A normal, healthy man at age 20 has a maximum capacity of approximately M_{act} = 12 met, which drops to 7 met at age 70. Maximum rates for women are on average about 30% lower. Long-distance runners and trained athletes have maximum rates as high as 20 met. An average 35-year-old who does not exercise has a maximum rate of about 10 met, and activities with M_{act} > 5 met are likely to prove exhausting.

Intermittent Activity. Often, people's activity consists of a mixture of activities or a combination of work/rest periods. A

Licensed for single user. © 2021 ASHRAE, Inc.

weighted average metabolic rate is generally satisfactory, provided that activities alternate frequently (several times per hour). For example, a person whose activities consist of typing 50% of the time, filing while seated 25% of the time, and walking about 25% of the time would have an average metabolic rate of 0.50 × 65 + 0.25 × 70 + 0.25 × 100 = 75 W/m^2 (see Table 4).

Accuracy. Estimating metabolic rates is difficult. Values given in Table 4 indicate metabolic rates only for the specific activities listed. Some entries give a range and some a single value, depending on the data source. The level of accuracy depends on the value of M_{act} and how well the activity can be defined. For well-defined activities with M_{act} < 1.5 met (e.g., reading), Table 4 is sufficiently accurate for most engineering purposes. For values of M_{act} > 3, where a task is poorly defined or where there are various ways of performing a task (e.g., heavy machine work), the values may be in error by as much as ±50% for a given application. Engineering calculations should thus allow for potential variations.

Measurement. When metabolic rates must be determined more accurately than is possible with tabulated data, physiological measurements with human subjects may be necessary. The rate of metabolic heat produced by the body is most accurately measured by the rate of respiratory oxygen consumption and carbon dioxide production. An empirical equation for metabolic rate is given by Nishi (1981):

$$M = \frac{21(0.23\mathrm{RQ} + 0.77)Q_{O_2}}{A_D} \tag{34}$$

where

M = metabolic rate, W/m^2
RQ = respiratory quotient; molar ratio of Q_{CO_2} exhaled to Q_{O_2} inhaled, dimensionless
Q_{O_2} = volumetric rate of oxygen consumption at conditions (STPD) of 0°C, 101.325 kPa, mL/s

The exact value of the respiratory quotient RQ depends on a person's activity, diet, and physical condition. It can be determined by measuring both carbon dioxide and oxygen in the respiratory airflows, or it can be estimated with reasonable accuracy. A good estimate for the average adult is RQ = 0.83 for light or sedentary activities (M < 1.5 met), increasing proportionately to RQ = 1.0 for extremely heavy exertion (M = 5.0 met). Estimating RQ is generally sufficient for all except precision laboratory measurements because it does not strongly affect the value of the metabolic rate: a 10% error in estimating RQ results in an error of less than 3% in the metabolic rate.

A second, much less accurate, method of estimating metabolic rate physiologically is to measure the heart rate. Table 5 shows the relationship between heart rate and oxygen consumption at different levels of physical exertion for a typical person. Once oxygen consumption is estimated from heart rate information, Equation (34) can be used to estimate the metabolic rate. Other factors that affect heart rate include physical condition, heat, emotional factors, and muscles used. Astrand and Rodahl (1977) show that heart rate is only a very approximate measure of metabolic rate and should not be the only source of information where accuracy is required.

Table 5 Heart Rate and Oxygen Consumption at Different Activity Levels

Level of Exertion	Heart Rate, bpm	Oxygen Consumed, mL/s
Light work	<90	<8
Moderate work	90 to 110	8 to 16
Heavy work	110 to 130	16 to 24
Very heavy work	130 to 150	24 to 32
Extremely heavy work	150 to 170	>32

Source: Astrand and Rodahl (1977).

Mechanical Efficiency. In the heat balance equation, the rate W of work accomplished must be in the same units as metabolism M and expressed in terms of A_D in W/m^2. The mechanical work done by the muscles for a given task is often expressed in terms of the body's mechanical efficiency $\mu = W/M$. It is unusual for μ to be more than 0.05 to 0.10; for most activities, it is close to zero. The maximum value under optimal conditions (e.g., bicycle ergometer) is μ = 0.20 to 0.24 (Nishi 1981). It is common to assume that mechanical work is zero for several reasons: (1) mechanical work produced is small compared to metabolic rate, especially for office activities; (2) estimates for metabolic rates are often inaccurate; and (3) this assumption gives a more conservative estimate when designing air-conditioning equipment for upper comfort and health limits. More accurate calculation of heat generation may require estimating mechanical work produced for activities where it is significant (walking on a grade, climbing a ladder, bicycling, lifting, etc.). In some cases, it is possible to either estimate or measure the mechanical work. For example, a 90 kg person walking up a 5% grade at 1.0 m/s would be lifting an 882 N (90 kg × 9.8 N/kg) weight over a height of 0.05 m every second, for a work rate of 44 (N·m)/s = 44 W. This rate of mechanical work would then be subtracted from M to determine the net heat generated.

Heat Transfer Coefficients

Values for the linearized radiative heat transfer coefficient, convective heat transfer coefficient, and evaporative heat transfer coefficient are required to solve the equations describing heat transfer from the body.

Radiative Heat Transfer Coefficient. The linearized radiative heat transfer coefficient can be calculated by

$$h_r = 4\varepsilon\sigma\frac{A_r}{A_D}\left(273.2 + \frac{t_{cl} + \bar{t}_r}{2}\right)^3 \tag{35}$$

where

h_r = radiative heat transfer coefficient, W/(m^2·K)
ε = average emissivity of clothing or body surface, dimensionless
σ = Stefan-Boltzmann constant, 5.67 × 10^{-8} W/(m^2·K^4)
A_r = effective radiation area of body, m^2

The ratio A_r/A_D is 0.70 for a sitting person and 0.73 for a standing person (Fanger 1967). Emissivity ε is close to unity (typically 0.95), unless special reflective materials are used or high-temperature sources are involved. It is not always possible to solve Equation (35) explicitly for h_r, because t_{cl} may also be unknown. Some form of iteration may be necessary if a precise solution is required. Fortunately, h_r is nearly constant for typical indoor temperatures, and a value of 4.7 W/(m^2·K) suffices for most calculations. If emissivity is significantly less than unity, adjust the value by

$$h_r = 4.7\varepsilon \tag{36}$$

where ε represents the area-weighted average emissivity for the clothing/body surface.

Convective Heat Transfer Coefficient. Heat transfer by convection is usually caused by air movement within the living space or by body movements. Equations for estimating h_c under various conditions are presented in Table 6. Where two conditions apply (e.g., walking in moving air), a reasonable estimate can be obtained by taking the larger of the two values for h_c. Limits have been given to all equations. If no limits were given in the source, reasonable limits have been estimated. Be careful using these values for seated and reclining persons. The heat transfer coefficients may be accurate, but the effective heat transfer area may be substantially reduced through body contact with a padded chair or bed.

Licensed for single user. © 2021 ASHRAE, Inc.

Table 6 Equations for Convection Heat Transfer Coefficients

Equation	Limits	Condition	Remarks/Sources
$h_c = 8.3V^{0.6}$ $h_c = 3.1$	$0.2 < V < 4.0$ $0 < V < 0.2$	Seated with moving air	Mitchell (1974)
$h_c = 2.7 + 8.7V^{0.67}$ $h_c = 5.1$	$0.15 < V < 1.5$ $0 < V < 0.15$	Reclining with moving air	Colin and Houdas (1967)
$h_c = 8.6V^{0.53}$	$0.5 < V < 2.0$	Walking in still air	V is walking speed (Nishi and Gagge 1970)
$h_c = 5.7(M - 0.8)^{0.39}$	$1.1 < M < 3.0$	Active in still air	Gagge et al. (1976)
$h_c = 6.5V^{0.39}$	$0.5 < V < 2.0$	Walking on treadmill in still air	V is treadmill speed (Nishi and Gagge 1970)
$h_c = 14.8V^{0.69}$ $h_c = 4.0$	$0.15 < V < 1.5$ $0 < V < 0.15$	Standing person in moving air	Developed from data presented by Seppänen et al. (1972)

Note: h_c in W/(m²·K), V in m/s, and M in met, where 1 met = 58.1 W/m².

Quantitative values of h_c are important, not only in estimating convection loss, but in evaluating (1) operative temperature t_o, (2) clothing parameters I_t and i_m, and (3) rational effective temperatures t_{oh} and ET*. All heat transfer coefficients in Table 6 were evaluated at or near 101.33 kPa. These coefficients should be corrected as follows for atmospheric pressure:

$$h_{cc} = h_c(p_t/101.33)^{0.55} \quad (37)$$

where

h_{cc} = corrected convective heat transfer coefficient, W/(m²·K)
p_t = local atmospheric pressure, kPa

The combined coefficient h is the sum of h_r and h_c, described in Equation (35) and Table 6, respectively. The coefficient h governs exchange by radiation and convection from the exposed body surface to the surrounding environment.

Evaporative Heat Transfer Coefficient. The evaporative heat transfer coefficient h_e for the outer air layer of a nude or clothed person can be estimated from the convective heat transfer coefficient using the Lewis relation given in Equation (27). If the atmospheric pressure is significantly different from the reference value (101.33 kPa), the correction to the value obtained from Equation (27) is

$$h_{ec} = h_e(101.33/p_t)^{0.45} \quad (38)$$

where h_{ec} is the corrected evaporative heat transfer coefficient in W/(m²·kPa).

Clothing Insulation and Permeation Efficiency

Thermal Insulation. The most accurate ways to determine clothing insulation are (1) measurements on heated mannikins (McCullough and Jones 1984; Olesen and Nielsen 1983) and (2) measurements on active subjects (Nishi et al. 1975). For most routine engineering work, estimates based on tables and equations in this section are sufficient. Thermal mannikins can measure the sensible heat loss from "skin" ($C + R$) in a given environment. Equation (11) can then be used to evaluate R_{cl} if environmental conditions are well defined and f_{cl} is measured. Evaluation of clothing insulation on subjects requires measurement of t_{sk}, t_{cl}, and t_o. Clothing thermal efficiency is calculated by

$$f_{cl} = \frac{t_{cl} - t_o}{t_{sk} - t_o} \quad (39)$$

Table 7 Typical Insulation and Permeability Values for Western Clothing Ensembles

Ensemble Description[a]	I_{cl}, clo	I_t,[b] clo	f_{cl}	i_{cl}	i_m[b]
Walking shorts, short-sleeved shirt	0.36	1.02	1.10	0.34	0.42

Overalls, long-sleeved shirt, T-shirt	0.89	1.46	1.27	0.35	0.40
Insulated coveralls, long-sleeved thermal underwear, long underwear bottoms	1.37	1.94	1.26	0.35	0.39

Source: From McCullough and Jones (1984) and McCullough et al. (1989).
[a]All ensembles include shoes and briefs or panties. All ensembles except those with panty hose include socks unless otherwise noted.
[b]For $t_r = t_a$ and air velocity less than 0.2 m/s (I_a = 0.72 clo and i_m = 0.48 when nude). 1 clo = 0.155 (m²·K/)W.

The intrinsic clothing insulation can then be calculated from mannikin measurements, provided f_{cl} is measured and conditions are sufficiently well defined to determine h accurately:

$$R_{cl} = \frac{t_{sk} - t_o}{q} - \frac{1}{hf_{cl}} \quad (40)$$

where q is heat loss from the mannikin in W/m².

Clothing insulation value may be expressed in clo units. To avoid confusion, the symbol I is used with the clo unit instead of the symbol R. The relationship between the two is

$$R = 0.155I \quad (41)$$

or 1.0 clo is equivalent to 0.155 (m²·K)/W.

Because clothing insulation cannot be measured for most routine engineering applications, tables of measured values for various clothing ensembles can be used to select an ensemble comparable to the one(s) in question. Table 7 gives values for typical indoor clothing ensembles. More detailed tables are presented by McCullough and Jones (1984) and Olesen and Nielsen (1983). Accuracies for I_{cl} on the order of ±20% are typical if good matches between ensembles are found. Values of thermal insulation and clothing area factors for clothing ensembles typical of the Arabian Gulf region may be found in Al-ajmi et al. (2008).

ASHRAE research project RP-1504 (Havenith et al. 2015) produced a database of static total and intrinsic clothing thermal insulation values and vapor permeability indices for non-Western ensembles. The report presents tabulated data for more than 40 ensembles from India, Pakistan, Indonesia, Kuwait, Nigeria, Ghana,

Licensed for single user. © 2021 ASHRAE, Inc.

and China. Table 8 gives values for a selection of these ensembles. Local regional thermal insulation values for the ensembles were also measured, together with data on the effects of air velocity, posture, and walking on the total thermal insulation values.

Table 8 Insulation and Permeability Values for a Selection of Non-Western Clothing Ensembles

Ensemble Description[a]	Country	I_{cl} clo	I_t, clo	f_{cl}	i_m
Shalwar (pants), kameez (shirt), scarf, sandals (f)	Pakistan	0.69	1.1	1.41	0.32
Shalwar (pants), kameez (shirt), socks, athletic shoes (m)	Pakistan	0.86	1.3	1.36	0.35
Dishdasha (thowb or caftan), short-sleeved t-shirt, long serwal (pants), tagiya (hat), iqal (cord), ghutra (headdress), socks, athletic shoes (m)	Kuwait	1.36	1.7	1.66	0.30
Full slip, double-layer abaya (dress), anta (head cover), hijab (headscarf), sandals (f)	Kuwait	1.27	1.7	1.65	0.33

Churidhar pants, churidhar dress, shawl, sandals (f)	India	0.58	1.1	1.28	0.36
Short shirt with long sleeves, long pants, boubou (wide-sleeved robe), kufi (hat), sandals (m)	Nigeria/ Ghana	1.40	1.7	1.96	0.42
Short shirt with long sleeves, long pants, sandals (f)	Nigeria/ Ghana	0.78	1.3	1.35	0.40
Long-sleeved shirt, skirt, headscarf, socks, athletic shoes (f)	Indonesia	0.97	1.4	1.43	0.31
Camisole, short-sleeved qipao (dress), sandals (f)	China	0.42	0.9	1.31	0.40

(f) = clothing traditionally worn by women
(m) = clothing traditionally worn by men
Source: Havenith et al. (2015). Values are the means of manikin-based measurements conducted in three laboratories. All ensembles include bra and panties (female) and briefs (male). For all women's ensembles, I_a = 0.64 clo; for all men's ensembles, I_a = 0.63 clo.

When a premeasured ensemble cannot be found to match the one in question, estimate the ensemble insulation from the insulation of individual garments. Table 9 lists common individual garments. The insulation of an ensemble is estimated from the individual values using a summation formula (McCullough and Jones 1984):

$$I_{cl} = 0.835 \sum_i I_{clu,i} + 0.161 \tag{42}$$

where $I_{clu,i}$ is the effective insulation of garment i, and I_{cl}, as before, is the insulation for the entire ensemble. A simpler and nearly as accurate summation formula is (Olesen 1985)

$$I_{cl} = \sum_i I_{clu,i} \tag{43}$$

Either Equation (42) or (43) gives acceptable accuracy for typical indoor clothing. The main source of inaccuracy is in determining the appropriate values for individual garments. Overall accuracies are on the order of ±25% if the tables are used carefully. If it is important to include a specific garment not included in Table 8, its insulation can be estimated by (McCullough and Jones 1984)

$$I_{clu,i} = (0.534 + 135x_f)(A_G/A_D) - 0.0549 \tag{44}$$

where

x_f = fabric thickness, mm
A_G = body surface area covered by garment, m^2

Values in Table 7 may be adjusted by information in Table 9 and a summation formula. Using this method, values of $I_{clu,i}$ for the selected items in Table 9 are then added to or subtracted from the ensemble value of I_{cl} in Table 7.

When a person is sitting, the chair generally has the effect of increasing clothing insulation by up to 0.15 clo, depending on the contact area A_{ch} between the chair and body (McCullough et al. 1994). A string webbed or beach chair has little or no contact area, and the insulation actually decreases by about 0.1 clo, likely because of compression of the clothing in the contact area. In contrast, a cushioned executive chair has a large contact area that can increase the intrinsic clothing insulation by 0.15 clo. For other chairs, the increase in intrinsic insulation ΔI_{cl} can be estimated from

Table 9 Garment Insulation Values

Garment Description[a]	$I_{clu,i}$, clo[b]	Garment Description[a]	$I_{clu,i}$, clo[b]	Garment Description[a]	$I_{clu,i}$, clo[b]

[a]"Thin" garments are summerweight; "thick" garments are winterweight. [b]1 clo = 0.155 (m^2·K)/W [c]Knee-length

Licensed for single user. © 2021 ASHRAE, Inc.

$$\Delta I_{cl} = 0.748A_{ch} - 0.1 \quad (45)$$

where A_{ch} is in m^2.

For example, a desk chair with a body contact area of 0.27 m^2 has a ΔI_{cl} of 0.1 clo. This amount should be added to the intrinsic insulation of the standing clothing ensemble to obtain the insulation of the ensemble when sitting in the desk chair.

Although sitting increases clothing insulation, walking decreases it (McCullough and Hong 1994), as does air movement (Havenith and Nilsson 2004). The change in clothing insulation ΔI_{cl} can be estimated from the standing intrinsic insulation I_{cl} of the ensemble and the walking speed (Walkspeed) in steps per minute:

$$\Delta I_{cl} = -0.504I_{cl} - 0.00281(\text{Walkspeed}) + 0.24 \quad (46)$$

For example, the clothing insulation of a person wearing a winter business suit with a standing intrinsic insulation of 1 clo would decrease by 0.52 clo when the person walks at 90 steps per minute (about 3.7 km/h). Thus, when the person is walking, the intrinsic insulation of the ensemble would be 0.48 clo.

A correction for both walking and air speed for a person in normal or light clothing (0.6 clo < I_{cl} < 1.4 clo, or 1.2 clo < I_T < 2.0 clo, respectively) is given by Havenith and Nilsson (2004) and Havenith et al. (2012) as

$$\begin{aligned} I_{cl,r} &= I_{T,r} - \frac{1}{f_{cl}\,0.155h} \\ &= \left[e^{\left[-0.281 \times (v_{ar} - 0.15) + 0.044 \times (v_{ar} - 0.15)^2 - 0.492w + 0.176w^2\right]} \right. \\ &\quad \left. \times \left(I_{cl,static} + \frac{0.7}{f_{cl}} \right) \right] \\ &\quad - \frac{(0.92e^{(-0.15v_{ar} - 0.22v_w)} - 0.0045)0.7}{f_{cl}} \end{aligned} \quad (47)$$

where

$I_{cl,r}$ = resultant intrinsic clothing insulation, clo
$I_{cl,static}$ = static intrinsic clothing insulation obtained from manikin or tables, clo
$I_{T,r}$ = resultant total insulation of clothing plus adjacent air layer
v_{ar} = wind speed relative to person, from 0.15 to 4 m/s (if above this range, treat as 4 m/s; if below this range, treat as 0.15 m/s)
v_w = walking speed, from 0 to 1.2 m/s (if above this range, treat as 1.2 m/s)

Permeation Efficiency. Permeation efficiency data for some clothing ensembles are presented in terms of i_{cl} and i_m in Table 7. Values of i_m can be used to calculate $R_{e,t}$ using the relationships in Table 2. Ensembles worn indoors generally fall in the range $0.3 < i_m < 0.5$. Assuming $i_m = 0.4$ is reasonably accurate (McCullough et al. 1989) and may be used if a good match to ensembles in Table 7 cannot be made. The value of i_m or $R_{e,t}$ may be substituted directly into equations for body heat loss calculations (see Table 3). However, i_m for a given clothing ensemble is a function of the environment as well as the clothing properties. Unless i_m is evaluated at conditions very similar to the intended application, it is more rigorous to use i_{cl} to describe the permeation efficiency of the clothing. The value of i_{cl} is not as sensitive to environmental conditions; thus, given data are more accurate over a wider range of air velocity and radiant and air temperature combinations for i_{cl} than for i_m. Relationships in Table 2 can be used to determine $R_{e,cl}$ from i_{cl}, and $R_{e,cl}$ can then be used for body heat loss calculations (see Table 3). McCullough et al. (1989) found an average value of i_{cl} = 0.34 for common indoor clothing; this value can be used when other data are not available.

Measuring i_m or i_{cl} may be necessary if unusual clothing (e.g., impermeable or metallized) and/or extreme environments (e.g., high radiant temperatures, high air velocities) are to be addressed. There are three different methods for measuring the permeation efficiency of clothing: (1) using a wet mannikin to measure the effect of sweat evaporation on heat loss (McCullough 1986), (2) using permeation efficiency measurements on component fabrics as well as dry mannikin measurements (Umbach 1980), and (3) using measurements from sweating subjects (Holmer 1984; Nishi et al. 1975). For an overview, please see ISO *Standard* 9920.

Clothing Surface Area. Many clothing heat transfer calculations require that clothing area factor f_{cl} be known. The most reliable approach is to measure it using photographic methods (Olesen et al. 1982). Other than actual measurements, the best method is to use previously tabulated data for similar clothing ensembles. Table 7 is adequate for most indoor clothing ensembles. No good method of estimating f_{cl} for an ensemble from other information is available, although a rough estimate can be made by (McCullough and Jones 1984)

$$f_{cl} = 1.0 + 0.3I_{cl} \quad (48)$$

Total Evaporative Heat Loss

The total evaporative heat loss (latent heat) from the body through both respiratory and skin losses, $E_{sk} + E_{res}$, can be measured directly from the body's rate of mass loss as observed by a sensitive scale:

$$E_{sk} + E_{res} = \frac{h_{fg}}{A_D} \times \frac{dm}{d\theta} \quad (49)$$

where

h_{fg} = latent heat of vaporization of water, J/kg
m = body mass, kg
θ = time, s

When using Equation (49), adjustments should be made for any food or drink consumed, body effluents (e.g., wastes), and metabolic mass losses. Metabolism contributes slightly to mass loss primarily because the oxygen absorbed during respiration is converted to heavier CO_2 and exhaled. It can be calculated by

$$\frac{dm_{ge}}{d\theta} = Q_{O2}(1.977\text{RQ} - 1.429)/10^6 \quad (50)$$

where

$dm_{ge}/d\theta$ = rate of mass loss due to respiratory gas exchange, kg/s
Q_{O_2} = oxygen uptake at STPD, mL/s
RQ = respiratory quotient
1.977 = density of CO_2 at STPD, kg/m^3
1.429 = density of O_2 at STPD, kg/m^3
STPD = standard temperature and pressure of dry air at 0°C and 101.325 kPa

Environmental Parameters

Thermal environment parameters that must be measured or otherwise quantified to obtain accurate estimates of human thermal response are divided into two groups: those that can be measured directly and those calculated from other measurements.

Directly Measured Parameters. Seven psychrometric parameters used to describe the thermal environment are (1) air temperature t_a, (2) wet-bulb temperature t_{wb}, (3) dew-point temperature t_{dp}, (4) water vapor pressure p_a, (5) total atmospheric pressure p_t, (6) relative humidity (rh), and (7) humidity ratio W_a. These parameters are discussed in detail in Chapter 1, and methods for measuring them are discussed in Chapter 37. Two other important

Licensed for single user. © 2021 ASHRAE, Inc.

parameters include air velocity V and mean radiant temperature $\bar{t}_r$. Air velocity measurements are also discussed in Chapter 37. The radiant temperature is the temperature of an exposed surface in the environment. The temperatures of individual surfaces are usually combined into a mean radiant temperature $\bar{t}_r$. Finally, globe temperature t_g, which can also be measured directly, is a good approximation of the operative temperature t_o and is also used with other measurements to calculate the mean radiant temperature.

Calculated Parameters. The **mean radiant temperature** $\bar{t}_r$ is a key variable in thermal calculations for the human body. It is the uniform temperature of an imaginary enclosure in which radiant heat transfer from the human body equals the radiant heat transfer in the actual nonuniform enclosure. Measurements of the globe temperature, air temperature, and air velocity can be combined to estimate the mean radiant temperature (see Chapter 37). Accuracy of $\bar{t}_r$ determined this way varies considerably, depending on the type of environment and accuracy of the individual measurements. Because the mean radiant temperature is defined with respect to the human body, the shape of the sensor is also a factor. The spherical shape of the globe thermometer gives a reasonable approximation of a seated person; an ellipsoid sensor gives a better approximation of the shape of a human, both upright and seated.

Mean radiant temperature can also be calculated from the measured temperature of surrounding walls and surfaces and their positions with respect to the person. Most building materials have a high emittance ε, so all surfaces in the room can be assumed to be black. The following equation is then used:

$$\bar{T}_r^4 = T_1^4 F_{p-1} + T_2^4 F_{p-2} + \cdots + T_N^4 F_{p-N} \tag{51}$$

where

$\bar{T}_r$ = mean radiant temperature, K
T_N = surface temperature of surface N, K
F_{p-N} = angle factor between a person and surface N

Because the sum of the angle factors is unity, the fourth power of mean radiant temperature equals the mean value of the surrounding surface temperatures to the fourth power, weighted by the respective angle factors. In general, angle factors are difficult to determine, although Figures 3A and 3B may be used to estimate them for rectangular surfaces. The angle factor normally depends on the position and orientation of the person (Fanger 1982).

If relatively small temperature differences exist between the surfaces of the enclosure, Equation (51) can be simplified to a linear form:

$$\bar{t}_r = t_1 F_{p-1} + t_2 F_{p-2} + \cdots + t_N F_{p-N} \tag{52}$$

Equation (52) always gives a slightly lower mean radiant temperature than Equation (51), but the difference is small. If, for example, half the surroundings ($F_{p-N} = 0.5$) has a temperature 5 K higher than the other half, the difference between the calculated mean radiant temperatures [according to Equations (51) and (52)] is only 0.2 K. If, however, this difference is 100 K, the mean radiant temperature calculated by Equation (52) is 10 K too low.

Mean radiant temperature may also be calculated from the plane radiant temperature t_{pr} in six directions (up, down, right, left, front, back) and for the projected area factors of a person in the same six directions. For a standing person, the mean radiant temperature may be estimated as

$$\begin{aligned}\bar{t}_r = {} & \{0.08[t_{pr}(\text{up}) + t_{pr}(\text{down})] + 0.23[t_{pr}(\text{right}) \\ & + t_{pr}(\text{left})] + 0.35[t_{pr}(\text{front}) + t_{pr}(\text{back})]\} \\ & \div [2(0.08 + 0.23 + 0.35)]\end{aligned} \tag{53}$$

For a seated person,

$$\begin{aligned}\bar{t}_r = {} & \{0.18[t_{pr}(\text{up}) + t_{pr}(\text{down})] + 0.22[t_{pr}(\text{right}) \\ & + t_{pr}(\text{left})] + 0.30[t_{pr}(\text{front}) + t_{pr}(\text{back})]\} \\ & \div [2(0.18 + 0.22 + 0.30)]\end{aligned} \tag{54}$$

The **plane radiant temperature** t_{pr}, introduced by Korsgaard (1949), is the uniform temperature of an enclosure in which the

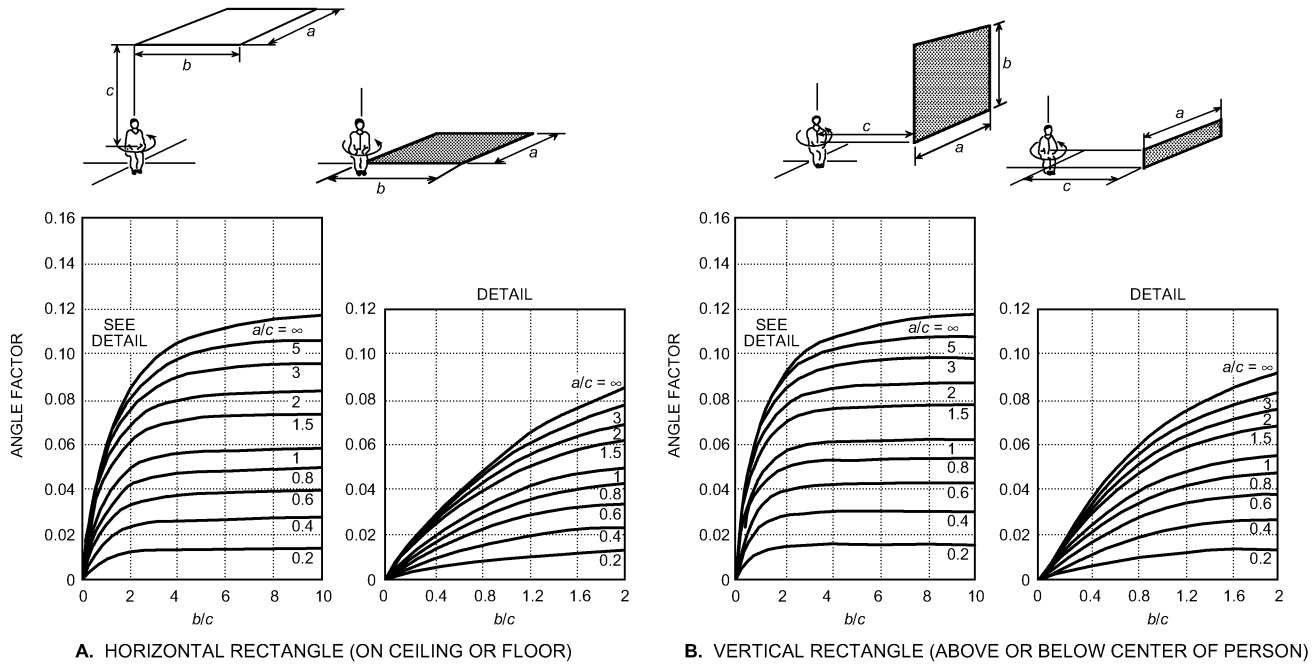

Fig. 3 Mean Value of Angle Factor Between Seated Person and Horizontal or Vertical Rectangle when Person Is Rotated Around Vertical Axis
(Fanger 1982)

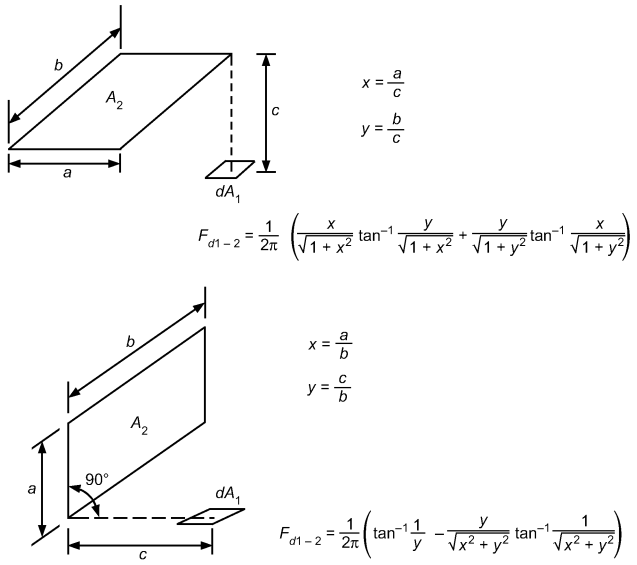

Fig. 4 Analytical Formulas for Calculating Angle Factor for Small Plane Element

incident radiant flux on one side of a small plane element is the same as that in the actual environment. The plane radiant temperature describes thermal radiation in one direction, and its value thus depends on the direction. In comparison, mean radiant temperature $\bar{t}_r$ describes the thermal radiation for the human body from all directions. The plane radiant temperature can be calculated using Equations (50) and (51) with the same limitations. Area factors are determined from Figure 4.

The **radiant temperature asymmetry** Δt_{pr} is the difference between the plane radiant temperature of the opposite sides of a small plane element. This parameter describes the asymmetry of the radiant environment and is especially important in comfort conditions. Because it is defined with respect to a plane element, its value depends on the plane's orientation, which may be specified in some situations (e.g., floor to ceiling asymmetry) and not in others. If direction is not specified, the radiant asymmetry should be for the orientation that gives the maximum value.

5. CONDITIONS FOR THERMAL COMFORT

In addition to the previously discussed independent environmental and personal variables influencing thermal response and comfort, other factors may also have some effect. These secondary factors include nonuniformity of the environment, visual stimuli, age, and outdoor climate. Studies by Rohles (1973) and Rohles and Nevins (1971) on 1600 college-age students revealed correlations between comfort level, temperature, humidity, sex, and length of exposure. Many of these correlations are given in Table 10. The thermal sensation scale developed for these studies is called the **ASHRAE thermal sensation scale**:

+3	hot
+2	warm
+1	slightly warm
0	neutral
−1	slightly cool
−2	cool
−3	cold

The equations in Table 10 indicate that women in this study were more sensitive to temperature and less sensitive to humidity than the men, but in general about a 3 K change in temperature or a 3 kPa change in water vapor pressure is necessary to change a thermal sensation vote by one unit or temperature category.

Table 10 Equations for Predicting Thermal Sensation *Y* of Men, Women, and Men and Women Combined

Exposure Period, h	Subjects	Regression Equations[a, b] *t* = dry-bulb temperature, °C *p* = vapor pressure, kPa
1.0	Men	$Y = 0.220\,t + 0.233\,p - 5.673$
	Women	$Y = 0.272\,t + 0.248\,p - 7.245$
	Both	$Y = 0.245\,t + 0.248\,p - 6.475$
2.0	Men	$Y = 0.221\,t + 0.270\,p - 6.024$
	Women	$Y = 0.283\,t + 0.210\,p - 7.694$
	Both	$Y = 0.252\,t + 0.240\,p - 6.859$
3.0	Men	$Y = 0.212\,t + 0.293\,p - 5.949$
	Women	$Y = 0.275\,t + 0.255\,p - 8.622$
	Both	$Y = 0.243\,t + 0.278\,p - 6.802$

[a] *Y* values refer to the ASHRAE thermal sensation scale.
[b] For young adult subjects with sedentary activity and wearing clothing with a thermal resistance of approximately 0.5 clo, $\bar{t}_r < t_a$ and air velocities < 0.2 m/s.

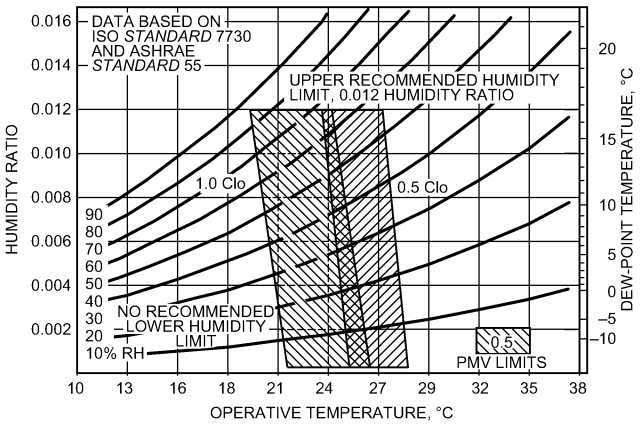

Fig. 5 ASHRAE Summer and Winter Comfort Zones
[Acceptable ranges of operative temperature and humidity with air speed ≤ 0.2 m/s for people wearing 1.0 and 0.5 clo clothing during primarily sedentary activity (≤1.1 met)].

Current and past studies are periodically reviewed to update ASHRAE *Standard* 55, which specifies conditions or comfort zones where 80% of sedentary or slightly active persons find the environment thermally acceptable. Examples of figures and calculation methods adapted from the standard are presented here to demonstrate the fundamentals and provide guidance in using the standard. In professional practice, the most recent version of the standard should be referenced.

Because people wear different levels of clothing depending on the situation and seasonal weather, ASHRAE *Standard* 55-2013 defines comfort zones for 0.5 and 1.0 clo [0.078 and 0.155 ($m^2 \cdot K$)/W] clothing levels similar to those in Figure 5. For reference, a winter business suit has about 1 clo of insulation, and a short-sleeved shirt and trousers have about 0.5 clo. The warmer and cooler temperature borders of the comfort zones are affected by humidity and coincide with lines of constant ET*. In the middle of a zone, a typical person wearing the prescribed clothing would have a thermal sensation at or very near neutral. Near the boundary of the warmer zone, a person would feel about +0.5 warmer on the ASHRAE thermal sensation scale; near the boundary of the cooler zone, that person may have a thermal sensation of −0.5.

Licensed for single user. © 2021 ASHRAE, Inc.

The comfort zone's temperature boundaries (T_{min}, T_{max}) can be adjusted by interpolation for clothing insulation levels (I_{cl}) between those in Figure 5 by using the following equations:

$$T_{min,I_{cl}} = \frac{(I_{cl} - 0.5\text{ clo})T_{min,1.0\text{ clo}} + (1.0\text{ clo} - I_{cl})T_{min,0.5\text{ clo}}}{0.5\text{ clo}} \quad (55)$$

$$T_{max,I_{cl}} = \frac{(I_{cl} - 0.5\text{ clo})T_{max,1.0\text{ clo}} + (1.0\text{ clo} - I_{cl})T_{max,0.5\text{ clo}}}{0.5\text{ clo}} \quad (56)$$

In general, comfort temperatures for other clothing levels can be approximated by decreasing the temperature borders of the zone by 0.6 K for each 0.1 clo increase in clothing insulation and vice versa. Similarly, a zone's temperatures can be decreased by 1.4 K per met increase in activity above 1.2 met.

The upper and lower humidity levels of the comfort zones are less precise, and ASHRAE *Standard* 55-2013 specifies no lower humidity limit for thermal comfort. Low humidity can dry the skin and mucous surfaces and lead to comfort complaints about dry nose, throat, eyes, and skin, typically when the dew point is less than 0°C. Liviana et al. (1988) found eye discomfort increased with time in low-humidity environments (dew point < 2°C). Green (1982) found that respiratory illness and absenteeism increase in winter with decreasing humidity and found that any increase in humidity from very low levels decreased absenteeism in winter.

At high humidity, too much skin moisture tends to increase discomfort (Berglund and Cunningham 1986; Gagge 1937), particularly skin moisture of physiological origin (water diffusion and perspiration). At high humidity, thermal sensation alone is not a reliable predictor of thermal comfort (Tanabe et al. 1987). The discomfort appears to be caused by the feeling of the moisture itself, increased friction between skin and clothing with skin moisture (Gwosdow et al. 1986), and other factors. To prevent warm discomfort, Nevins et al. (1975) recommended that, on the warm side of the comfort zone, the relative humidity not exceed 60%.

ASHRAE *Standard* 55-2013 specifies an upper humidity ratio limit of 0.012 $kg_w/kg_{dry\ air}$, which corresponds to a dew point of 16.8°C at standard pressure. This limit can be exceeded under certain circumstances if the standard's analytical comfort zone method is used.

The comfort zones of Figure 5 are for air speeds not to exceed 0.2 m/s. However, elevated air speeds can be used to improve comfort beyond the maximum temperature limit of this figure. The air speeds necessary to compensate for a temperature increase above the warm-temperature border are shown in Figure 6. The combination of air speed and temperature defined by the curves in this figure result in the same heat loss from the skin.

The amount of air speed increase is affected by the mean radiant temperature $\bar{t}_r$. The curves of Figure 6 are for different levels of $\bar{t}_r - t_a$. That is, when the mean radiant temperature is low and the air temperature is high, elevated air speed is less effective at increasing heat loss and a higher air speed is needed for a given temperature increase. Conversely, elevated air speed is more effective when the mean radiant temperature is high and air temperature is low; then, less of an air speed increase is needed. Figure 6 applies to lightly clothed individuals (clothing insulation between 0.5 and 0.7 clo) who are engaged in near-sedentary physical activity. The elevated air speed may be used to offset an increase in temperature by up to 3 K above the warm-temperature boundary of Figure 5.

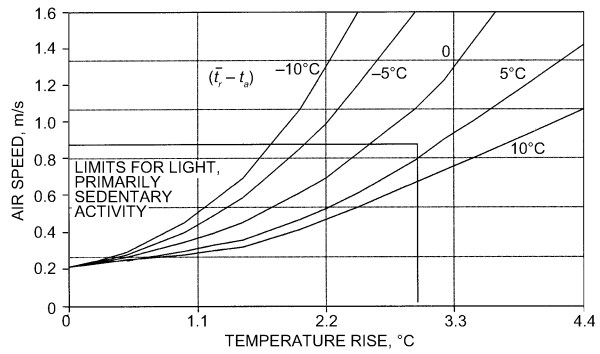

Fig. 6 Air Speed to Offset Temperatures Above Warm-Temperature Boundaries of Figure 5

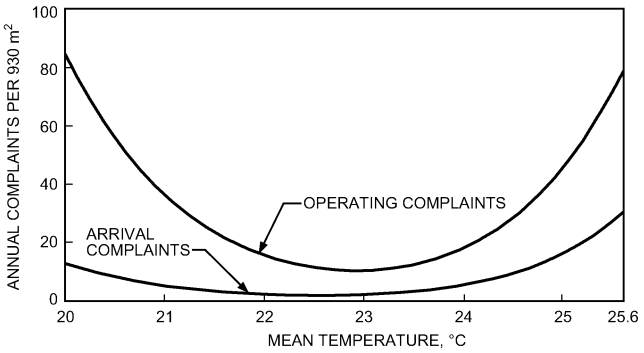

Fig. 7 Predicted Rate of Unsolicited Thermal Operating Complaints

Thermal Complaints

Unsolicited thermal complaints can increase a building's operation and maintenance (O&M) cost by requiring unscheduled maintenance to correct the problem.

Federspiel (1998) analyzed complaint data from 690 commercial buildings with a total of 23 500 occupants. The most common kind of unsolicited complaint was of temperature extremes. Complaints were rarely because of individual differences in preferred temperature, because 96.5% of the complaints occurred at temperatures less than 21°C or greater than 24°C; most complaints were caused by HVAC faults or poor control performance.

The hourly complaint rate per zone area of being too hot (ν_h) or too cold (ν_l) can be predicted from the HVAC system's operating parameters, specifically the mean space temperature (μ_T), standard deviation of the space temperature (σ_T), and the standard deviation of the rate of change in space temperature ($\sigma_{\dot{T}_H}$, $\sigma_{\dot{T}_L}$):

$$\nu_h = \frac{1}{2\pi}\left(\frac{\sigma_{\dot{T}_H}^2 + \sigma_{\dot{T}_B}^2}{\sigma_{T_H}^2 + \sigma_{T_B}^2}\right)^{1/2} \exp\left(-\frac{1}{2}\frac{(\mu_{T_B} - \mu_{T_H})^2}{(\sigma_{T_H}^2 + \sigma_{T_B}^2)}\right) \quad (57)$$

$$\nu_l = \frac{1}{2\pi}\left(\frac{\sigma_{\dot{T}_L}^2 + \sigma_{\dot{T}_B}^2}{\sigma_{T_L}^2 + \sigma_{T_B}^2}\right)^{1/2} \exp\left(-\frac{1}{2}\frac{(\mu_{T_B} - \mu_{T_L})^2}{(\sigma_{T_L}^2 + \sigma_{T_B}^2)}\right) \quad (58)$$

where the subscripts *H*, *L*, and *B* refer to too hot, too cold, and building (Federspiel 2001).

Table 11 Model Parameters

Zone, m^2	μ_{T_H}, °C	σ_{T_H}, K	σ_{T_H}, K/h	μ_{T_L}, °C	σ_{T_L}, K	σ_{T_L}, K/h
430	32.8	2.81	0.63	10.24	3.41	2.27

The building maintenance and space temperature records of six commercial buildings in Minneapolis, Seattle, and San Francisco were analyzed for the values of the *H* and *L* model parameters (Federspiel et al. 2003) of Table 11. Complaint rates predicted by the model for these building parameters are graphed in Figure 7. **Arrival complaints** occur when the temperature exceeds either the hot or cold complaint level when occupants arrive in the morning. **Operating complaints** occur during the occupied period when the temperature crosses above the hot complaint level or below the cold complaint level. Arriving occupants generally have a higher metabolic power because of recent activity (e.g., walking).

Complaint prediction models can be used to determine the minimum discomfort temperature (MDT) setting that minimizes the occurrences of thermal complaints for a building with known or measured HVAC system parameters σ_{T_B} and σ_{T_B}. Similarly, complaint models can be used with building energy models and service call costs to determine the minimum cost temperature (MCT) where the operating costs are minimized. For example, the summer MDT and MCT in Sacramento, California, are 22.8 and 25°C for a commercial building at design conditions with σ_{T_B} = 0.3 K and σ_{T_B} = 0.6 . For these conditions, temperatures below 22.8°C increase both cold complaints and energy costs, and those above 25°C increase hot complaints and costs. Thus, the economically logical acceptable temperature range for this building is 22.8 to 25°C for minimum operating cost and discomfort (Federspiel et al. 2003).

6. THERMAL COMFORT AND TASK PERFORMANCE

The generally held belief that improving indoor environmental quality enhances productivity often depends on indirect evidence, because direct evidence is difficult to obtain (Levin 1995). However, numerous studies have measured performance over a wide range of tasks and indoor environments [e.g., Berglund et al. (1990); Link and Pepler (1970); Niemelä et al. (2001); Pepler and Warner (1968); Roelofsen (2001); Seppänen et al. (2006); Wyon (1996)]. Task performance is generally highest at comfort conditions (Gonzalez 1975; Griffiths and McIntyre 1975), and a range of temperature at comfort conditions exists within which there is no significant further effect on performance (Federspiel 2001; Federspiel et al. 2002; McCartney and Humphreys 2002; Witterseh 2001).

Twenty-four studies were analyzed and normalized to quantify and generalize the effects of room temperature as a surrogate for thermal comfort on office task performance (Seppänen and Fisk 2006). Of these, 11 were field studies with data collected in working offices and 9 were conducted in controlled laboratory environments.

Most of the office field studies were performed in call centers; in these studies, the speed of work (e.g., average time per call) was used as a measure of work performance. Laboratory studies typically assessed work performance by evaluating the speed and accuracy with which subjects performed tasks, such as text processing and simple calculations, simulating aspects of office work.

The percentage of performance change per degree increase in temperature was calculated for all studies, positive values indicating increases in performance with increasing temperature, and negative values indicating decreases in performance with increasing temperature. A weighted average of the measured performance changes per degree change results in the curve shown in Figure 8. In averaging the measurements, work done by subjects in office field studies was assumed more representative of overall real-world performance and was weighted higher than performance changes in simulated computerized tasks.

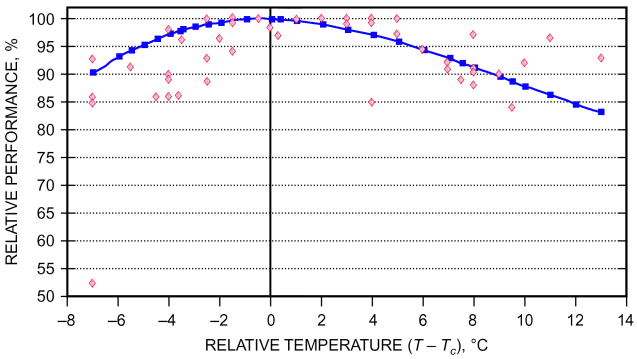

Fig. 8 Relative Performance of Office Work Performance versus Deviation from Optimal Comfort Temperature T_c

Data points from 11 of the studies are also shown in Figure 8. Note the large amount of scatter in the individual studies about the line, indicating a high level of uncertainty.

However, as a first approximation, the performance versus temperature relationship in the graph may still be useful as a general representation of real-world office work performance for the tasks performed in the studies, and helpful as a guide in design, operation, and cost analysis.

The results show that performance decreases as temperature deviates above or below a thermal comfort temperature range. As shown in Figure 8, at a temperature 8 K higher than optimal, average office task performance decreased to about 91% of the value at optimum temperature.

7. THERMAL NONUNIFORM CONDITIONS AND LOCAL DISCOMFORT

A person may feel thermally neutral as a whole but still feel uncomfortable if one or more parts of the body are too warm or too cold. Nonuniformities may be caused by a cold window, a hot surface, a draft, or a temporal variation of these. Even small variations in heat flow cause the thermal regulatory system to compensate, thus increasing the physiological effort of maintaining body temperatures. The boundaries of the comfort zones (see Figure 5) of ASHRAE *Standard* 55 provide a thermal acceptability level of 90% if the environment is thermally uniform. Because the standard's objective is to specify conditions for 80% acceptability, the standard allows nonuniformities to decrease acceptability by 10%. Fortunately for the designer and user, the effect of common thermal nonuniformities on comfort is quantifiable and predictable, as discussed in the following sections. Furthermore, most humans are fairly insensitive to small nonuniformities.

Asymmetric Thermal Radiation

Asymmetric or nonuniform thermal radiation in a space may be caused by cold windows, uninsulated walls, cold products, cold or warm machinery, or improperly sized heating panels on the wall or ceiling. In residential buildings, offices, restaurants, etc., the most common causes are cold windows or improperly sized or installed ceiling heating panels. At industrial workplaces, the reasons include cold or warm products, cold or warm equipment, etc.

Recommendations in ISO *Standard* 7730 and ASHRAE *Standard* 55 are based primarily on studies reported by Fanger et al. (1980). These standards include guidelines regarding the radiant temperature asymmetry from an overhead warm surface (heated ceiling) and a vertical cold surface (cold window). Among the studies conducted on the influence of asymmetric thermal radiation are

Licensed for single user. © 2021 ASHRAE, Inc.

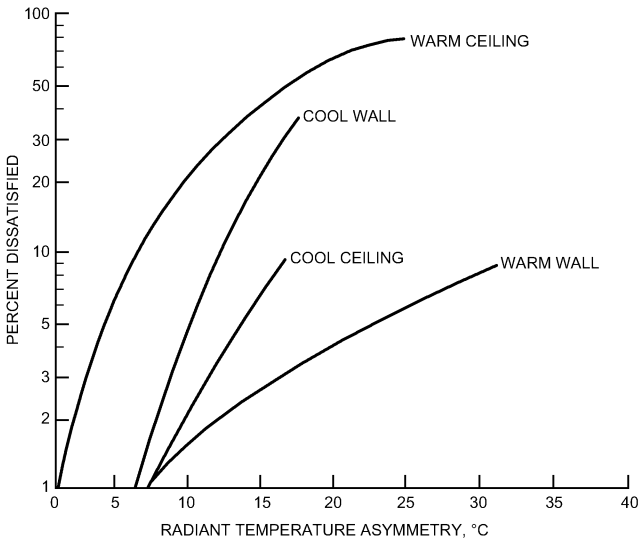

Fig. 9 Percentage of People Expressing Discomfort Caused by Asymmetric Radiation

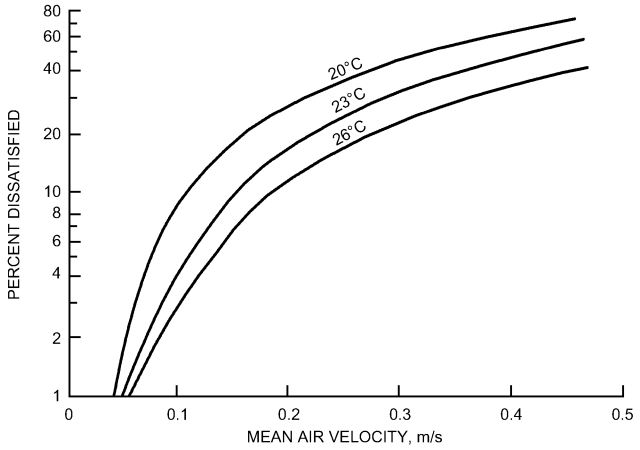

Fig. 10 Percentage of People Dissatisfied as Function of Mean Air Velocity

those by Fanger and Langkilde (1975), McIntyre (1974, 1976), McIntyre and Griffiths (1975), McNall and Biddison (1970), and Olesen et al. (1972). These studies all used seated subjects, who were always in thermal neutrality and exposed only to the discomfort resulting from excessive asymmetry.

The subjects gave their reactions on their comfort sensation, and a relationship between the radiant temperature asymmetry and the number of subjects feeling dissatisfied was established (Figure 9). Radiant asymmetry, as defined in the section on Environmental Parameters, is the difference in radiant temperature of the environment on opposite sides of the person. More precisely, radiant asymmetry is the difference in radiant temperatures seen by a small flat element looking in opposite directions.

Figure 9 shows that people are more sensitive to asymmetry caused by an overhead warm surface than by a vertical cold surface. The influence of an overhead cold surface or a vertical warm surface is much less. These data are particularly important when using radiant panels to provide comfort in spaces with large cold surfaces or cold windows.

Loveday et al. (1998) used a series of controlled climate chamber studies to establish the design conditions required for thermal comfort for sedentary subjects conducting office work in combined chilled-ceiling and displacement ventilation environments. As part of this study, Hodder et al. (1998) found that the vertical radiant temperature asymmetry for the typical range of ceiling temperatures (22 to 12.5°C) encountered in practice in these combination environments had no effect on the overall thermal comfort of the seated occupants, and that existing guidance regarding toleration of radiant asymmetry in these environments remains valid.

Other studies of clothed persons in neutral environments found thermal acceptability unaffected by radiant temperature asymmetries of 10 K or less (Berglund and Fobelets 1987) and comfort unaffected by asymmetries of 20 K or less (McIntyre and Griffiths 1975).

Draft

Draft is an undesired local cooling of the human body caused by air movement. This is a serious problem, not only in many ventilated buildings but also in automobiles, trains, and aircraft. Draft has been identified as one of the most annoying factors in offices. When people sense draft, they often demand higher air temperatures in the room or that ventilation systems be stopped.

Fanger and Christensen (1986) aimed to establish the percentage of the population feeling draft when exposed to a given mean velocity. Figure 10 shows the percentage of subjects who felt draft on the head region (the dissatisfied) as a function of mean air velocity at the neck. The head region comprises head, neck, shoulders, and back. Air temperature significantly influenced the percentage of dissatisfied. There was no significant difference between responses of men and women. The data in Figure 10 apply only to persons wearing normal indoor clothing and performing light, mainly sedentary work. Persons with higher activity levels are not as sensitive to draft (Jones et al. 1986).

A study of the effect of air velocity over the whole body found thermal acceptability unaffected in neutral environments by air speeds of 0.25 m/s or less (Berglund and Fobelets 1987). This study also found no interaction between air speed and radiant temperature asymmetry on subjective responses. Thus, acceptability changes and the percent dissatisfied because of draft and radiant asymmetry are independent and additive.

Fanger et al. (1989) investigated the effect of turbulence intensity on sensation of draft. Turbulence intensity significantly affects draft sensation, as predicted by the following model. This model can be used to quantify draft risk in spaces and to develop air distribution systems with a low draft risk.

$$PD = (34 - t_a)(V - 0.05)^{0.62}(0.37V\,Tu + 3.14) \quad (59)$$

where PD is percent dissatisfied and Tu is the turbulence intensity (in percent) defined by

$$Tu = 100\,\frac{V_{sd}}{V} \quad (60)$$

For $V < 0.05$ m/s, insert $V = 0.05$, and for PD > 100%, insert PD = 100%. V_{sd} is the standard deviation of the velocity measured with an omnidirectional anemometer having a 0.2 s time constant.

The model extends the Fanger and Christensen (1986) draft chart model to include turbulence intensity. In this study, Tu decreases when V increases. Thus, the effects of V for the experimental data to which the model is fitted are $20 < t_a < 26$°C, $0.05 < V < 0.5$ m/s, and $0 < Tu < 70$%. Figure 11 gives more precisely the curves that result from intersections between planes of constant Tu and the surfaces of PD = 15%.

At thermal conditions above neutrality, air movement can be beneficial for thermal comfort. Arens et al. (2009) found people prefer more air movement under some conditions in office spaces.

Licensed for single user. © 2021 ASHRAE, Inc.

Applications of this include ceiling fans and personal environmental control systems in offices and transportation systems.

Vertical Air Temperature Difference

In most buildings, air temperature normally increases with height above the floor. If the gradient is sufficiently large, local warm discomfort can occur at the head and/or cold discomfort can occur at the feet, although the body as a whole is thermally neutral. Among the few studies of vertical air temperature differences and the influence of thermal comfort reported are Eriksson (1975), McNair (1973), McNair and Fishman (1974), and Olesen et al. (1979). Subjects were seated in a climatic chamber and individually exposed to different air temperature differences between head and ankles (Olesen et al. 1979). During the tests, the subjects were in thermal neutrality because they were allowed to change the temperature level in the test room whenever they desired; the vertical temperature difference, however, was kept unchanged. Subjects gave subjective reactions to their thermal sensation; Figure 12 shows the percentage of dissatisfied as a function of the vertical air temperature difference between head (1.1 m above the floor) and ankles (0.1 m above the floor).

A head-level air temperature lower than that at ankle level is not as critical for occupants. Eriksson (1975) indicated that subjects could tolerate much greater differences if the head were cooler. This observation is verified in experiments with asymmetric thermal radiation from a cooled ceiling (Fanger et al. 1985).

Warm or Cold Floors

Because of direct contact between the feet and the floor, local discomfort of the feet can often be caused by a too-high or too-low floor temperature. Also, floor temperature significantly influences a room's mean radiant temperature. Floor temperature is greatly affected by building construction (e.g., insulation of the floor, above a basement, directly on the ground, above another room, use of floor heating, floors in radiant-heated areas). If a floor is too cold and the occupants feel cold discomfort in their feet, a common reaction is to increase the temperature level in the room; in the heating season, this also increases energy consumption. A radiant system, which radiates heat from the floor, can also prevent discomfort from cold floors.

The most extensive studies of the influence of floor temperature on foot comfort were performed by Olesen (1977a, 1977b), who, based on his own experiments and reanalysis of data from Nevins and Feyerherm (1967), Nevins and Flinner (1958), and Nevins et al. (1964), found that flooring material is important for people with bare feet (e.g., in swimming halls, gymnasiums, dressing rooms, bathrooms, bedrooms). Ranges for some typical floor materials are as follows:

Textiles (rugs)	21 to 28°C
Pine floor	22.5 to 28°C
Oak floor	24.5 to 28°C
Hard linoleum	24 to 28°C
Concrete	26 to 28.5°C

To save energy, insulating flooring materials (cork, wood, carpets), radiant heated floors, or floor heating systems can be used to eliminate the desire for higher ambient temperatures caused by cold feet. These recommendations should also be followed in schools, where children often play directly on the floor.

For people wearing normal indoor footwear, flooring material is insignificant. Olesen (1977b) found an optimal temperature of 25°C for sedentary and 23°C for standing or walking persons. At the optimal temperature, 6% of occupants felt warm or cold discomfort in the feet. Figure 13 shows the relationship between floor temperature and percent dissatisfied, combining data from experiments with seated and standing subjects. In all experiments, subjects were in thermal neutrality; thus, the percentage of dissatisfied is only related to discomfort caused by cold or warm feet. No significant difference in preferred floor temperature was found between females and males.

8. SECONDARY FACTORS AFFECTING COMFORT

Temperature, air speed, humidity, their variation, and personal parameters of metabolism and clothing insulation are primary factors that directly affect energy flow and thermal comfort. However, many secondary factors, some of which are discussed in this section, may more subtly influence comfort.

Day-to-Day Variations

Fanger (1973) determined the preferred ambient temperature for each of a group of subjects under identical conditions on four different days. Because the standard deviation was only 0.6 K, Fanger concluded that comfort conditions for an individual can be reproduced and vary only slightly from day to day.

Age

Because metabolism decreases slightly with age, many have stated that comfort conditions based on experiments with young and healthy subjects cannot be used for other age groups. Fanger (1982), Fanger and Langkilde (1975), Langkilde (1979), Nevins et al. (1966), and Rohles and Johnson (1972) conducted comfort studies in Denmark and the United States on different age groups (mean ages 21 to 84). The studies revealed that the thermal environments preferred by older people do not differ from those preferred by younger people. The lower metabolism in older people is compensated for by a lower evaporative loss. Collins and Hoinville (1980) confirmed these results.

The fact that young and old people prefer the same thermal environment does not necessarily mean that they are equally sensitive to cold or heat. In practice, the ambient temperature level in the homes of older people is often higher than that for younger people. This may be explained by the lower activity level of elderly people, who are normally sedentary for a greater part of the day.

Adaptation

Many believe that people can acclimatize themselves by exposure to hot or cold surroundings, so that they prefer other thermal environments. Fanger (1982) conducted experiments involving subjects from the United States, Denmark, and tropical countries. The latter group was tested in Copenhagen immediately after their arrival by plane from the tropics, where they had lived all their lives. Other experiments were conducted for two groups exposed to cold daily. One group comprised subjects who had been doing sedentary work in cold surroundings (in the meat-packing industry) for 8 h daily for at least 1 year. The other group consisted of winter swimmers who bathed in the sea daily.

Only slight differences in preferred ambient temperature and physiological parameters in the comfort conditions were reported for the various groups. These results indicate that people cannot adapt to preferring warmer or colder environments, and therefore the same comfort conditions can likely be applied throughout the world. However, in determining the preferred ambient temperature from the comfort equations, a clo-value corresponding to local clothing habits should be used, such as those given in Table 8 and in Havenith et al. (2015). A comparison of field comfort studies from different parts of the world shows significant differences in clothing habits depending on, among other things, outdoor climate (Nicol and Humphreys 1972). According to these results, adaptation has little influence on preferred ambient temperature. In uncomfortable warm or cold environments, however, adaptation often has an influence. People used to working and living in warm climates can more easily accept and maintain a higher work performance in hot environments than people from colder climates.

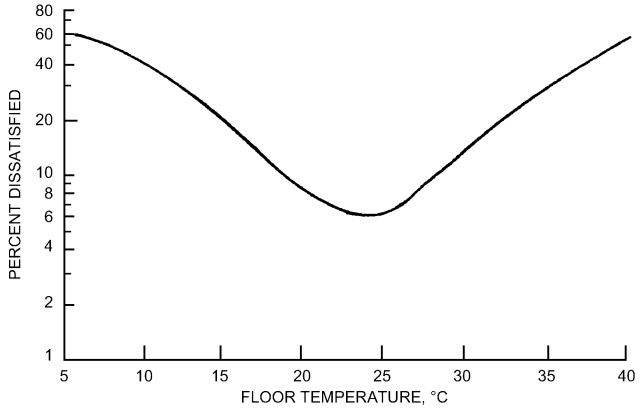

Fig. 13 Percentage of People Dissatisfied as Function of Floor Temperature

Sex

Fanger (1982), Fanger and Langkilde (1975), and Nevins et al. (1966) used equal numbers of male and female subjects, so comfort conditions for the two sexes can be compared. The experiments show that men and women prefer almost the same thermal environments. Women's skin temperature and evaporative loss are slightly lower than those for men, and this balances the somewhat lower metabolism of women. The reason that women often prefer higher ambient temperatures than men may be partly explained by the lighter clothing often worn by women.

Seasonal and Circadian Rhythms

Because people cannot adapt to prefer warmer or colder environments, it follows that there is no difference between comfort conditions in winter and in summer. McNall et al. (1968) confirmed this in an investigation where results of winter and summer experiments showed no difference. On the other hand, it is reasonable to expect comfort conditions to alter during the day because internal body temperature has a daily rhythm, with a maximum late in the afternoon, and a minimum early in the morning.

In determining the preferred ambient temperature for each of 16 subjects both in the morning and in the evening, Fanger et al. (1974) and Ostberg and McNicholl (1973) observed no difference. Furthermore, Fanger et al. (1973) found only small fluctuations in preferred ambient temperature during a simulated 8 h workday (sedentary work). There is a slight tendency to prefer somewhat warmer surroundings before lunch, but none of the fluctuations are significant.

9. PREDICTION OF THERMAL COMFORT

Thermal comfort and thermal sensation can be predicted several ways. One way is to use Figure 5 and Table 10 and adjust for clothing and activity levels that differ from those of the figure. More numerical and rigorous predictions are possible by using the PMV-PPD and two-node models described in this section.

Steady-State Energy Balance

Fanger (1982) related comfort data to physiological variables. At a given level of metabolic activity M, and when the body is not far from thermal neutrality, mean skin temperature t_{sk} and sweat rate E_{rsw} are the only physiological parameters influencing heat balance. However, heat balance alone is not sufficient to establish thermal comfort. In the wide range of environmental conditions where heat balance can be obtained, only a narrow range provides thermal comfort. The following linear regression equations, based on data from Rohles and Nevins (1971), indicate values of t_{sk} and E_{rsw} that provide thermal comfort:

$$t_{sk,req} = 35.7 - 0.0275(M - W) \quad (61)$$

$$E_{rsw,req} = 0.42\ (M - W - 58.15) \quad (62)$$

At higher activity levels, sweat loss increases and mean skin temperature decreases, both of which increase heat loss from the body

Licensed for single user. © 2021 ASHRAE, Inc.

core to the environment. These two empirical relationships link the physiological and heat flow equations and thermal comfort perceptions. By substituting these values into Equation (11) for $C + R$, and into Equations (17) and (18) for E_{sk}, Equation (1) (the energy balance equation) can be used to determine combinations of the six environmental and personal parameters that optimize comfort for steady-state conditions.

Fanger (1982) reduced these relationships to a single equation, which assumed all sweat generated is evaporated, eliminating clothing permeation efficiency i_{cl} as a factor in the equation. This assumption is valid for normal indoor clothing worn in typical indoor environments with low or moderate activity levels. At higher activity levels ($M_{act} > 3$ met), where a significant amount of sweating occurs even at optimum comfort conditions, this assumption may limit accuracy. The reduced equation is slightly different from the heat transfer equations developed here. The radiant heat exchange is expressed in terms of the Stefan-Boltzmann law (instead of using h_r), and diffusion of water vapor through the skin is expressed as a diffusivity coefficient and a linear approximation for saturated vapor pressure evaluated at t_{sk}. The combination of environmental and personal variables that produces a neutral sensation may be expressed as follows:

$$\begin{aligned} M - W = {} & 3.96 \times 10^{-8} f_{cl}[(t_{cl} + 273)^4 - (\bar{t}_r + 273)^4] + f_{cl} h_c (t_{cl} - t_a) \\ & + 3.05[5.73 - 0.007(M - W) - p_a] \\ & + 0.42[(M - W) - 58.15] + 0.0173M(5.87 - p_a) \\ & + 0.0014M(34 - t_a) \end{aligned} \quad (63)$$

where

$$\begin{aligned} t_{cl} = {} & 35.7 - 0.0275(M - W) - R_{cl}\{(M - W) \\ & - 3.05[5.73 - 0.007(M - W) - p_a] \\ & - 0.42[(M - W) - 58.15] - 0.0173M(5.87 - p_a) \\ & - 0.0014M(34 - t_a)\} \end{aligned} \quad (64)$$

The values of h_c and f_{cl} can be estimated from tables and equations given in the section on Engineering Data and Measurements. Fanger used the following relationships:

$$h_c = \begin{cases} 2.38(t_{cl} - t_a)^{0.25} & 2.38(t_{cl} - t_a)^{0.25} > 12.1\sqrt{V} \\ 12.1\sqrt{V} & 2.38(t_{cl} - t_a)^{0.25} < 12.1\sqrt{V} \end{cases} \quad (65)$$

$$f_{cl} = \begin{cases} 1.0 + 0.2I_{cl} & I_{cl} < 0.5 \text{ clo} \\ 1.05 + 0.1I_{cl} & I_{cl} > 0.5 \text{ clo} \end{cases} \quad (66)$$

Figures 14 and 15 show examples of how Equation (63) can be used.

Equation (63) is expanded to include a range of thermal sensations by using a **predicted mean vote (PMV) index**. The PMV index predicts the mean response of a large group of people according to the ASHRAE thermal sensation scale. Fanger (1970) related PMV to the imbalance between actual heat flow from the body in a given environment and the heat flow required for optimum comfort at the specified activity by the following equation:

$$\text{PMV} = [0.303 \exp(-0.036M) + 0.028]L \quad (67)$$

where L is the thermal load on the body, defined as the difference between internal heat production and heat loss to the actual environment for a person hypothetically kept at comfort values of t_{sk} and E_{rsw} at the actual activity level. Thermal load L is then the difference between the left and right sides of Equation (63) calculated for the actual values of the environmental conditions. As part of this calculation, clothing temperature t_{cl} is found by iteration as

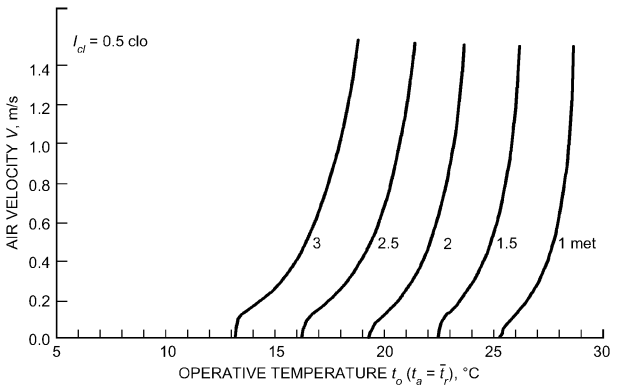

Fig. 14 Air Velocities and Operative Temperatures at 50% rh Necessary for Comfort (PMV = 0) of Persons in Summer Clothing at Various Levels of Activity

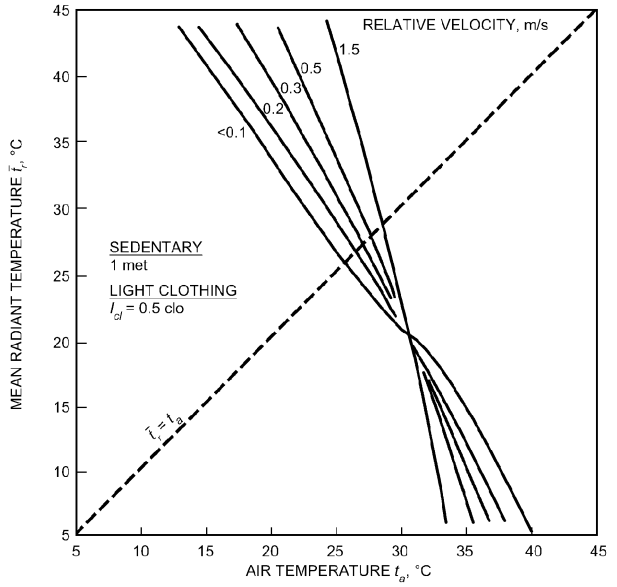

Fig. 15 Air Temperatures and Mean Radiant Temperatures Necessary for Comfort (PMV = 0) of Sedentary Persons in Summer Clothing at 50% rh

$$\begin{aligned} t_{cl} = {} & 35.7 - 0.028(M - W) \\ & - R_{cl}\{39.6 \times 10^{-9} f_{cl}[(t_{cl} + 273)^4 - (\bar{t}_r + 273)^4] \\ & + f_{cl} h_c (t_{cl} - t_a)\} \end{aligned} \quad (68)$$

After estimating the PMV with Equation (67) or another method, the **predicted percent dissatisfied (PPD)** with a condition can also be estimated. Fanger (1982) related the PPD to the PMV as follows:

$$\text{PPD} = 100 - 95 \exp[-(0.03353\text{PMV}^4 + 0.2179\text{PMV}^2)] \quad (69)$$

where dissatisfied is defined as anybody not voting –1, +1, or 0. This relationship is shown in Figure 16. A PPD of 10% corresponds to the PMV range of ±0.5, and even with PMV = 0, about 5% of the people are dissatisfied.

The **PMV-PPD model** is widely used and accepted for design and field assessment of comfort conditions. ISO *Standard* 7730 includes a short computer listing that facilitates computing PMV and PPD for a wide range of parameters.

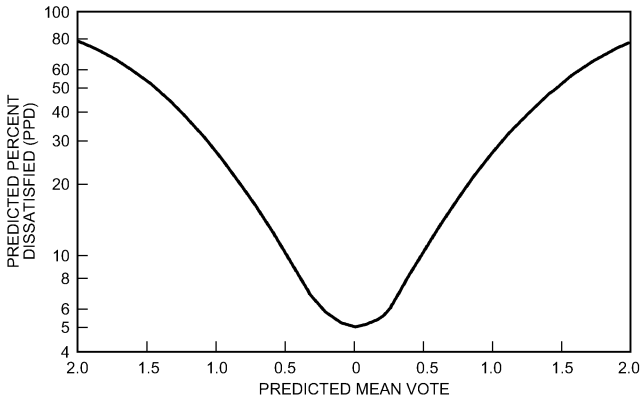

Fig. 16 Predicted Percentage of Dissatisfied (PPD) as Function of Predicted Mean Vote (PMV)

Two-Node Model

The PMV model is useful only for predicting steady-state comfort responses. The two-node model can be used to predict physiological responses or responses to transient situations, at least for low and moderate activity levels in cool to very hot environments (Gagge et al. 1971a, 1986). This model is a simplification of thermoregulatory models developed by Stolwijk and Hardy (1966). The simple, lumped parameter model considers a human as two concentric thermal compartments that represent the skin and the core of the body.

The **skin compartment** simulates the epidermis and dermis and is about 1.6 mm thick. Its mass, which is about 10% of the total body, depends on the amount of blood flowing through it for thermoregulation. Compartment temperature is assumed to be uniform so that the only temperature gradients are between compartments. In a cold environment, blood flow to the extremities may be reduced to conserve the heat of vital organs, resulting in axial temperature gradients in the arms, legs, hands, and feet. Heavy exercise with certain muscle groups or asymmetric environmental conditions may also cause nonuniform compartment temperatures and limit the model's accuracy.

All the heat is assumed to be generated in the **core compartment**. In the cold, shivering and muscle tension may generate additional metabolic heat. This increase is related to skin and core temperature depressions from their set point values, or

$$M_{shiv} = [156(37 - t_c) + 47(33 - t_{sk}) - 1.57(33 - t_{sk})^2]/\mathrm{BF}^{0.5} \quad (70)$$

where BF is percentage body fat and the temperature difference terms are set to zero if they become negative (Tikusis and Giesbrecht 1999).

The core loses energy when the muscles do work on the surroundings. Heat is also lost from the core through respiration. The rate of respiratory heat loss depends on sensible and latent changes in respired air and the ventilation rate as in Equations (19) and (20).

In addition, heat is conducted passively from the core to the skin. This is modeled as a massless thermal conductor [$K = 5.28$ W/(m^2·K)]. A controllable heat loss path from the core consists of pumping variable amounts of warm blood to the skin for cooling. This peripheral blood flow Q_{bl} in L/(h·m^2) depends on skin and core temperature deviations from their respective set points:

$$Q_{bl} = \frac{\mathrm{BFN} + c_{dil}(t_{cr} - 37)}{1 + S_{tr}(34 - t_{sk})} \quad (71)$$

The temperature terms can only be > 0. If the deviation is negative, the term is set to zero. For average persons, the coefficients BFN, c_{dil}, and S_{tr} are 6.3, 50, and 0.5. Further, skin blood flow Q_{bl} is limited to a maximum of 90 L/(h·m^2). A very fit and well-trained athlete could expect to have $c_{dil} = 175$.

Dry (sensible) heat loss q_{dry} from the skin flows through the clothing by conduction and then by parallel paths to the air and surrounding surfaces. Evaporative heat follows a similar path, flowing through the clothing and through the air boundary layer. Maximum evaporation E_{max} occurs if the skin is completely covered with sweat. The actual evaporation rate E_{sw} depends on the size w of the sweat film:

$$E_{sw} = wE_{max} \quad (72)$$

where w is E_{rsw}/E_{max}.

The rate of regulatory sweating E_{rsw} (rate at which water is brought to the surface of the skin in W/m) can be predicted by skin and core temperature deviations from their set points:

$$E_{rsw} = c_{sw}(t_b - t_{bset})\exp[(t_{sk} - 34)/10.7] \quad (73)$$

where $t_b = (1 - \alpha_{sk})t_{cr} + \alpha_{sk}t_{sk}$ and is the mean body temperature, $t_{bset} = 36.49$°C, and $c_{sw} = 116$ W/(m^2·K). The temperature deviation terms are set to zero when negative. The fraction of the total body mass considered to be thermally in the skin compartment is α_{sk}:

$$\alpha_{sk} = 0.0418 + \frac{0.745}{Q_{bl} + 0.585} \quad (74)$$

Regulatory sweating Q_{rsw} in the model is limited to 1 L/(h·m^2) or 670 W/m^2. E_{rsw} evaporates from the skin, but if E_{rsw} is greater than E_{max}, the excess drips off.

An energy balance on the core yields

$$M + M_{shiv} = W + q_{res} + (K + \mathrm{SkBF}c_{p,bl})(t_{cr} - t_{sk}) + m_{cr}c_{cr}\frac{\mathrm{d}t_{cr}}{\mathrm{d}\theta} \quad (75)$$

and for the skin,

$$(K + \mathrm{SkBF}c_{p,bl})(t_{cr} - t_{sk}) = q_{dry} + q_{evap} + m_{sk}c_{sk}\frac{\mathrm{d}t_{sk}}{\mathrm{d}\theta} \quad (76)$$

where c_{cr}, c_{sk}, and $c_{p,bl}$ are specific heats of core, skin, and blood [3500, 3500, and 4190 J/(kg·K), respectively], and SkBF is $\rho_{bl}Q_{bl}$, where ρ_{bl} is density of blood (1.06 kg/L).

Equations (75) and (76) can be rearranged in terms of $dt_{sk}/d\theta$ and $dt_{cr}/d\theta$ and numerically integrated with small time steps (10 to 60 s) from initial conditions or previous values to find t_{cr} and t_{sk} at any time.

After calculating values of t_{sk}, t_{cr}, and w, the model uses empirical expressions to predict thermal sensation (TSENS) and thermal discomfort (DISC). These indices are based on 11-point numerical scales, where positive values represent the warm side of neutral sensation or comfort, and negative values represent the cool side. TSENS is based on the same scale as PMV, but with extra terms for ±4 (very hot/cold) and ±5 (intolerably hot/cold). Recognizing the same positive/negative convention for warm/cold discomfort, DISC is defined as

5 intolerable
4 limited tolerance
3 very uncomfortable
2 uncomfortable and unpleasant
1 slightly uncomfortable but acceptable
0 comfortable

Licensed for single user. © 2021 ASHRAE, Inc.

TSENS is defined in terms of deviations of mean body temperature t_b from cold and hot set points representing the lower and upper limits for the zone of evaporative regulation: $t_{b,c}$ and $t_{b,h}$, respectively. The values of these set points depend on the net rate of internal heat production and are calculated by

$$t_{b,c} = \frac{0.194}{58.15}(M - W) + 36.301 \quad (77)$$

$$t_{b,h} = \frac{0.347}{58.15}(M - W) + 36.669 \quad (78)$$

TSENS is then determined by

$$\text{TSENS} = \begin{cases} 0.4685(t_b - t_{b,c}) & t_b < t_{b,c} \\ 4.7\eta_{ev}(t_b - t_{b,c})/(t_{b,h} - t_{b,c}) & t_{b,c} \le t_b \le t_{b,h} \\ 4.7\eta_{ev} + 0.4685(t_b - t_{b,h}) & t_{b,h} < t_b \end{cases} \quad (79)$$

where η_{ev} is the evaporative efficiency (assumed to be 0.85).

DISC is numerically equal to TSENS when t_b is below its cold set point $t_{b,c}$ and it is related to skin wettedness when body temperature is regulated by sweating:

$$\text{DISC} = \begin{cases} 0.4685(t_b - t_{b,c}) & t_b < t_{b,c} \\ \dfrac{4.7(E_{rsw} - E_{rsw,req})}{E_{max} - E_{rsw,req} - E_{dif}} & t_{b,c} \le t_b \end{cases} \quad (80)$$

where $E_{rsw,req}$ is calculated as in Fanger's model, using Equation (62).

Multisegment Thermal Physiology and Comfort Models

Unlike the two-node model, which represents the body as one cylinder with two nodes of core and skin, multisegment models divide the body into more segments (e.g., head, chest, hands, feet) and more tissue layers (e.g., core, muscle, fat, skin). They are intended to predict thermal physiology and thermal comfort in nonuniform [e.g., offices with displacement ventilation or underfloor air, radiant-cooled ceiling/floors, or natural and mixed-mode ventilation; personal environmental control (PEC) systems] and transient (e.g., occupants moving between different environments in offices, quick-responding PECs, automobiles) environments. Major multisegment physiological models include Fiala (1998), Fiala et al. (2003), Gordon (1974), Huizenga et al. (2001), Kraning and Gonzalez (1997), Smith (1991), Stolwijk (1971), Tanabe et al. (2002), Werner and Webb (1993), and Wissler (1964, 1985, 1988). These models mostly use finite-difference or finite-element methods, and include active thermoregulatory control in addition to passive heat transfer. They predict skin temperature for several local body segments, and central core temperature. They also predict other physiological parameters, such as segment sweat rate and skin wettedness, shivering, and cardiac blood flow.

Comfort is independently predicted from the output of physiological models. One comfort model, based on a review of literature addressing human sensation testing, uses an average of local skin temperatures and its time derivative to predict whole-body thermal sensation under stable and transient environments (Fiala 1998; Fiala et al. 2003). Another model uses the heat storage rate of the skin or core to predict whole-body thermal sensation under stable and transient environments (Wang 1994; Wang and Peterson 1992). The Berkeley comfort model predicts thermal sensation and comfort for each segment as well as for the whole body, using local skin temperatures, core temperature, and their time derivatives (Zhang 2003; Zhang et al. 2010a, 2010b, 2010c).

The equivalent homogeneous temperature (EHT) approach uses segmented electrical manikin measurements to determine the equivalent uniform environment for each body part (Nilsson 2007; Wyon et al. 1989). From these, comfortable environmental temperature ranges have been defined for each of the body segments. The EHT can determine comfort under nonuniform environments that are at steady state.

Adaptive Models

Adaptive models do not actually predict comfort responses but rather the almost constant conditions under which people are likely to be comfortable in buildings. In general, people naturally adapt and may also make various adjustments to themselves and their surroundings to reduce discomfort and physiological strain. It has been observed that, through adaptive actions, an acceptable degree of comfort in residences and offices is possible over a range of air temperatures from about 17 to 31°C (Humphreys and Nicol 1998).

Adaptive adjustments are typically conscious actions such as altering clothing, posture, activity schedules or levels, rate of working, diet, ventilation, air movement, and local temperature. They may also include unconscious longer-term changes to physiological set points and gains for control of shivering, skin blood flow, and sweating, as well as adjustments to body fluid levels and salt loss. However, only limited documentation and information on such changes is available.

An important driving force behind the adaptive process is the pattern of outdoor weather conditions and exposure to them. This is the principal input to adaptive models, which predict likely comfort temperatures t_c or ranges of t_c from monthly mean outdoor temperatures t_{out}. Humphreys and Nicol's (1998) model is based on data from a wide range of buildings, climates, and cultures:

$$t_c = 24.2 + 0.43(t_{out} - 22)\exp - \left(\frac{t_{out} - 22}{24\sqrt{2}}\right)^2 \quad (81)$$

Adaptive models are useful to guide design and energy decisions, and to specify building temperature set points throughout the year. An ASHRAE-sponsored study (de Dear and Brager 1998) on adaptive models compiled an extensive database from field studies to study, develop, and test adaptive models. For climates and buildings where cooling and central heating are not required, the study suggests the following model:

$$t_{oc} = 17.8 + 0.31t_{out} \quad (82)$$

where t_{oc} is the operative comfort temperature. The adaptive model boundary temperatures for 90% thermal acceptability are approximately t_{oc}+ 2.5°C and t_{oc} – 2.2°C according to ASHRAE *Standard* 55-2013.

In general, the value of using an adaptive model to specify set points or guide temperature control strategies is likely to increase with the freedom that occupants are given to adapt (e.g., by having flexible working hours, locations, or dress codes).

Zones of Comfort and Discomfort

The Two-Node Model section shows that comfort and thermal sensation are not necessarily the same variable, especially for a person in the zone of evaporative thermal regulation. Figures 17 and 18 show this difference for the standard combination of met-clo-air movement used in the standard effective temperature ET*. Figure 17 demonstrates that practically all basic physiological variables predicted by the two-node model are functions of ambient temperature and are relatively independent of vapor pressure. All exceptions occur at relative humidities above 80% and as the isotherms reach the ET* = 41.5°C line, where regulation by evaporation fails. Figure 18 shows that lines of constant ET* and wettedness are functions of both ambient temperature and vapor pressure. Thus, human thermal responses are divided into two classes: those in Figure 17, which respond only to heat stress from the environment, and those in

Licensed for single user. © 2021 ASHRAE, Inc.

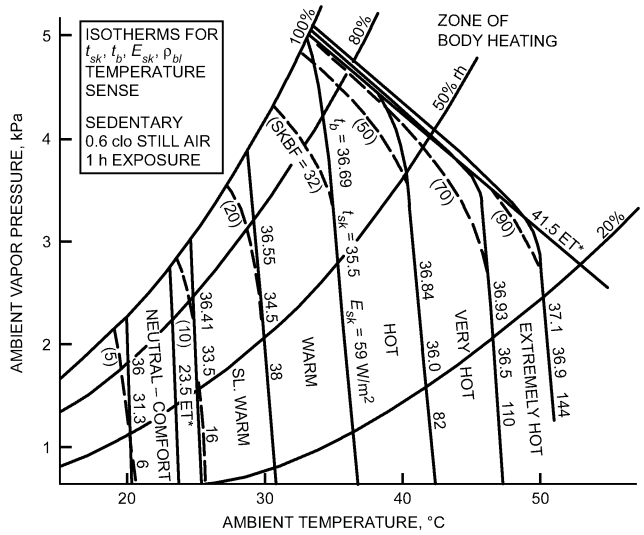

Fig. 17 Effect of Environmental Conditions on Physiological Variables

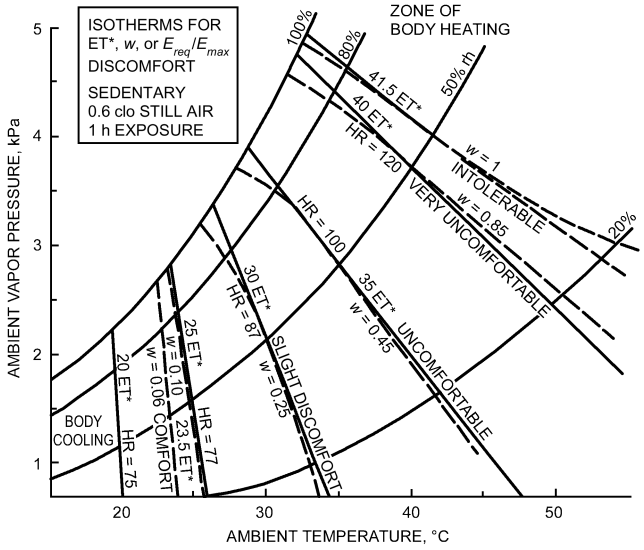

Fig. 18 Effect of Thermal Environment on Discomfort

Figure 18, which respond to both heat stress from the environment and the resultant heat strain (Stolwijk et al. 1968).

For warm environments, any index with isotherms parallel to skin temperature is a reliable index of thermal sensation alone, and not of discomfort caused by increased humidity. Indices with isotherms parallel to ET* are reliable indicators of discomfort or dissatisfaction with thermal environments. For a fixed exposure time to cold, lines of constant t_{sk}, ET*, and t_o are essentially identical, and cold sensation is no different from cold discomfort. For a state of comfort with sedentary or light activity, lines of constant t_{sk} and ET* coincide. Thus, comfort and thermal sensations coincide in this region as well. The upper and lower temperature limits for comfort at these levels can be specified either by thermal sensation (Fanger 1982) or by ET*, as is done in ASHRAE *Standard* 55, because lines of constant comfort and lines of co0nstant thermal sensation should be identical.

10. ENVIRONMENTAL INDICES

An environmental index combines two or more parameters (e.g., air temperature, mean radiant temperature, humidity, air velocity) into a single variable. Indices simplify description of the thermal environment and the stress it imposes. Environmental indices may be classified according to how they are developed. Rational indices are based on the theoretical concepts presented earlier. Empirical indices are based on measurements with subjects or on simplified relationships that do not necessarily follow theory. Indices may also be classified according to their application, generally either heat stress or cold stress.

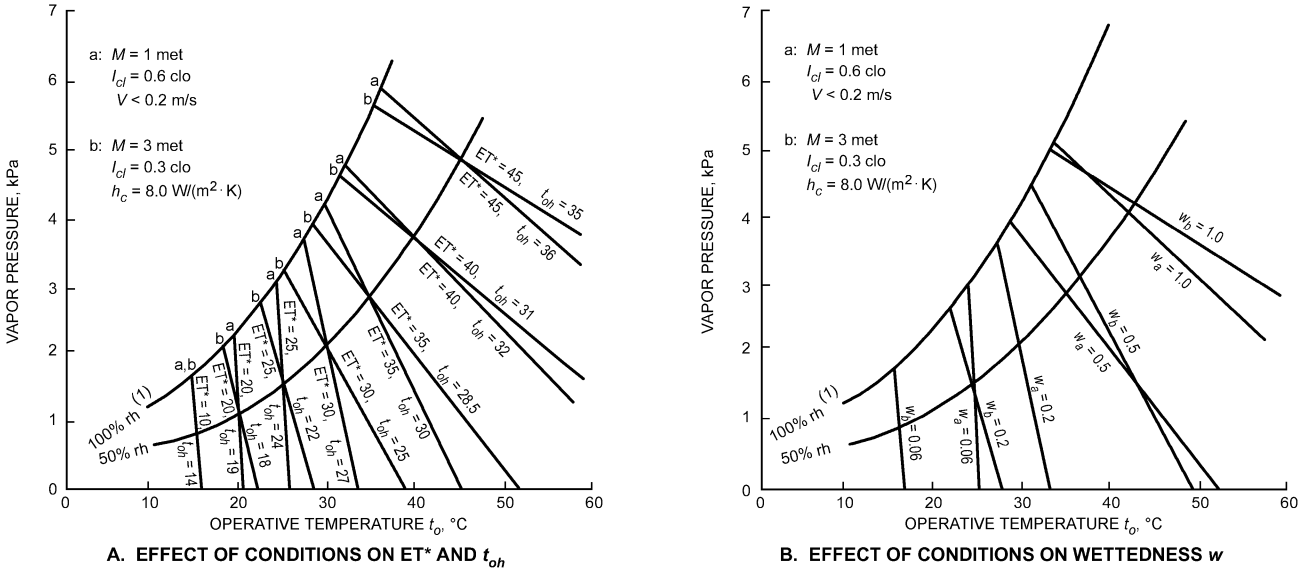
Effective Temperature

Effective temperature ET* is probably the most common environmental index, and has the widest range of application. It combines temperature and humidity into a single index, so two environments with the same ET* should evoke the same thermal response even though they have different temperatures and humidities, as long as they have the same air velocities.

The original empirical effective temperature was developed by Houghten and Yaglou (1923). Gagge et al. (1971a, 1971b) defined a new effective temperature using a rational approach. Defined mathematically in Equation (33), this is the temperature of an environment at 50% rh that results in the same total heat loss E_{sk} from the skin as in the actual environment.

Because the index is defined in terms of operative temperature t_o, it combines the effects of three parameters ($\bar{t}_r$, t_a, and p_a) into a single index. Skin wettedness w and the permeability index i_m must be specified and are constant for a given ET* line for a particular situation. The two-node model is used to determine skin wettedness in the zone of evaporative regulation. At the upper limit of regulation, w approaches 1.0; at the lower limit, w approaches 0.06. Skin wettedness equals one of these values when the body is outside the zone of evaporative regulation. Because the slope of a constant ET* line depends on skin wettedness and clothing moisture permeability, effective temperature for a given temperature and humidity may depend on the person's clothing and activity. This difference is shown in Figure 19. At low skin wettedness, air humidity has little influence, and lines of constant ET* are nearly vertical. As skin wettedness increases because of activity and/or heat stress, the lines become more horizontal and the influence of humidity is much more pronounced. The ASHRAE comfort envelope shown in Figure 5 is described in terms of ET*.

Because ET* depends on clothing and activity, it is not possible to generate a universal ET* chart. A standard set of conditions representative of typical indoor applications is used to define a **standard effective temperature SET***, defined as the equivalent air temperature of an isothermal environment at 50% rh in which a subject, wearing clothing standardized for the activity concerned, has the same heat stress (skin temperature t_{sk}) and thermoregulatory strain (skin wettedness w) as in the actual environment.



Humid Operative Temperature

The **humid operative temperature t_{oh}** is the temperature of a uniform environment at 100% rh in which a person loses the same total amount of heat from the skin as in the actual environment. This index is defined mathematically in Equation (32). It is analogous to ET*, except that it is defined at 100% rh and 0% rh rather than at 50% rh. Figures 2 and 19 indicate that lines of constant ET* are also lines of constant t_{oh}. However, the values of these two indices differ for a given environment.

Heat Stress Index

Originally proposed by Belding and Hatch (1955), this rational index is the ratio of total evaporative heat loss E_{sk} required for

[Adapted from Gonzalez et al. (1978) and Nishi et al. (1975)]

Table 12 Evaluation of Heat Stress Index

Heat Stress Index	Physiological and Hygienic Implications of 8 h Exposures to Various Heat Stresses
0	*No* thermal strain.
10 20 30	*Mild to moderate* heat strain. If job involves higher intellectual functions, dexterity, or alertness, subtle to substantial decrements in performance may be expected. In performing heavy physical work, little decrement is expected, unless ability of individuals to perform such work under no thermal stress is marginal.
40 50 60	*Severe* heat strain involving a threat to health unless workers are physically fit. Break-in period required for men not previously acclimatized. Some decrement in performance of physical work is to be expected. Medical selection of personnel desirable, because these conditions are unsuitable for those with cardiovascular or respiratory impairment or with chronic dermatitis. These working conditions are also unsuitable for activities requiring sustained mental effort.
70 80 90	*Very severe* heat strain. Only a small percentage of the population may be expected to qualify for this work. Personnel should be selected (a) by medical examination, and (b) by trial on the job (after acclimatization). Special measures are needed to ensure adequate water and salt intake. Amelioration of working conditions by any feasible means is highly desirable, and may be expected to decrease the health hazard while increasing job efficiency. Slight "indisposition," which in most jobs would be insufficient to affect performance, may render workers unfit for this exposure.
100	The *maximum* strain tolerated daily by fit, acclimatized young men.

thermal equilibrium (the sum of metabolism plus dry heat load) to maximum evaporative heat loss E_{max} possible for the environment, multiplied by 100, for steady-state conditions (S_{sk} and S_{cr} are zero) and with t_{sk} held constant at 35°C. The ratio E_{sk}/E_{max} equals skin wettedness w [Equation (18)]. When **heat stress index (HSI)** > 100, body heating occurs; when HSI < 0, body cooling occurs. Belding and Hatch (1955) limited E_{max} to 700 W/m², which corresponds to a sweat rate of approximately 280 mg/(s·m²). When t_{sk} is constant, loci of constant HSI coincide with lines of constant ET* on a psychrometric chart. Other indices based on wettedness have the same applications (Belding 1970; Gonzalez et al. 1978; ISO *Standard* 7933) but differ in their treatment of E_{max} and the effect of clothing. Table 12 describes physiological factors associated with HSI values.

Index of Skin Wettedness

Skin wettedness w is the ratio of observed skin sweating E_{sk} to the E_{max} of the environment as defined by t_{sk}, t_a, humidity, air movement, and clothing in Equation (12). Except for the factor of 100, it is essentially the same as HSI. Skin wettedness is more closely related to the sense of discomfort or unpleasantness than to temperature sensation (Gagge et al. 1969a, 1969b; Gonzalez et al. 1978).

Wet-Bulb Globe Temperature

The WBGT is an environmental heat stress index that combines dry-bulb temperature t_{db}, a **naturally ventilated** (not aspirated) wet-bulb temperature t_{nwb}, and black globe temperature t_g, according to the relation (Dukes-Dobos and Henschel 1971, 1973)

$$\text{WBGT} = 0.7t_{nwb} + 0.2t_g + 0.1t_a \quad (83)$$

This form of the equation is usually used where solar radiation is present. The naturally ventilated wet-bulb thermometer is left exposed to sunlight, but the air temperature t_a sensor is shaded. In enclosed environments, Equation (83) is simplified by dropping the t_a term and using a 0.3 weighting factor for t_g.

The black globe thermometer responds to air temperature, mean radiant temperature, and air movement, whereas the naturally ventilated wet-bulb thermometer responds to air humidity, air movement, radiant temperature, and air temperature. Thus, WBGT is a function of all four environmental factors affecting human environmental heat stress.

The WBGT index is widely used for estimating the heat stress potential of industrial environments (Davis 1976). In the United States, the National Institute of Occupational Safety and Health (NIOSH) developed criteria for a heat-stress-limiting standard

Licensed for single user. © 2021 ASHRAE, Inc.

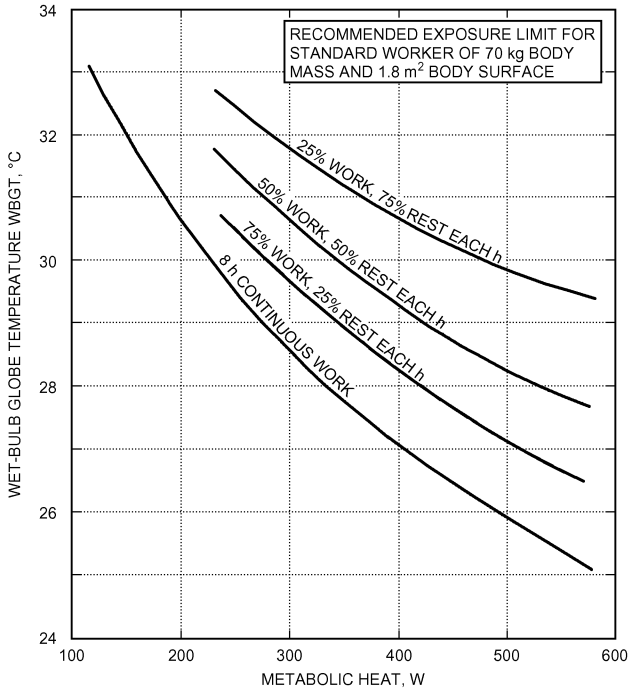

Fig. 20 Recommended Heat Stress Exposure Limits for Heat Acclimatized Workers
[Adapted from NIOSH (1986)]

(NIOSH 1986). ISO *Standard* 7243 also uses the WBGT. Figure 20 summarizes permissible heat exposure limits, expressed as working time per hour, for a fit individual, as specified for various WBGT levels. Values apply for normal permeable clothing (0.6 clo) and must be adjusted for heavy or partly vapor-permeable clothing. For example, the U.S. Air Force (USAF) recommended adjusting the measured WBGT upwards by 6 K for personnel wearing chemical protective clothing or body armor. This type of clothing increases resistance to sweat evaporation about threefold (higher if it is totally impermeable), requiring an adjustment in WBGT level to compensate for reduced evaporative cooling at the skin.

Several mathematical models are available for predicting WBGT from environmental factors: air temperature, psychrometric wet-bulb temperature, mean radiant temperature, and air motion (Azer and Hsu 1977; Sullivan and Gorton 1976).

Wet-Globe Temperature

The WGT, introduced by Botsford (1971), is a simpler approach to measuring environmental heat stress than the WBGT. The measurement is made with a wetted globe thermometer called a Botsball, which consists of a 65 mm black copper sphere covered with a fitted wet black mesh fabric, into which the sensor of a dial thermometer is inserted. A polished stem attached to the sphere supports the thermometer and contains a water reservoir for keeping the sphere covering wet. This instrument is suspended by the stem at the site to be measured.

Onkaram et al. (1980) showed that WBGT can be predicted with reasonable accuracy from WGT for temperate to warm environments with medium to high humidities. With air temperatures between 20 and 35°C, dew points from 7 to 25°C (relative humidities above 30%), and wind speeds of 7 m/s or less, the experimental regression equation (r = 0.98) in °C for an outdoor environment is

$$\text{WBGT} = 1.044(\text{WGT}) - 0.187 \quad (84)$$

This equation should not be used outside the experimental range given because data from hot/dry desert environments show differences between WBGT and WGT that are too large (6 K and above) to be adjusted by Equation (84) (Matthew et al. 1986). At very low humidity and high wind, WGT approaches the psychrometric wet-bulb temperature, which is greatly depressed below t_a. However, in the WBGT, t_{nwb} accounts for only 70% of the index value, with the remaining 30% at or above t_a.

Wind Chill Index

The wind chill index (WCI) is an empirical index developed from cooling measurements obtained in Antarctica on a cylindrical flask partly filled with water (Siple and Passel 1945). The index describes the rate of heat loss from the cylinder by radiation and convection for a surface temperature of 33°C, as a function of ambient temperature and wind velocity. As originally proposed,

$$\text{WCI} = (10.45 + 10\sqrt{V} - V)(33 - t_a) \text{ in kcal/(h·m}^2\text{)} \quad (85)$$

where V and t_a are in m/s and °C, respectively. Multiply WCI by 1.163 to convert to W/m^2. The 33°C surface temperature was chosen to be representative of the mean skin temperature of a resting human in comfortable surroundings.

Some valid objections have been raised about this formulation. Cooling rate data from which it was derived were measured on a 57 mm diameter plastic cylinder, making it unlikely that WCI would be an accurate measure of heat loss from exposed flesh, which has different characteristics from plastic (curvature, roughness, and radiation exchange properties) and is invariably below 33°C in a cold environment. Moreover, values given by the equation peak at 90 km/h, then decrease with increasing velocity.

Nevertheless, for velocities below 80 km/h, this index reliably expresses combined effects of temperature and wind on subjective discomfort. For example, if the calculated WCI is less than 1400 kcal/(h·m^2) and actual air temperature is above –10°C, there is little risk of frostbite during brief exposures (1 h or less), even for bare skin. However, at a WCI of 2000 or more, the probability is high that exposed flesh will begin to freeze in 1 min or less unless measures are taken to shield exposed skin (such as a fur ruff to break up wind around the face).

Rather than using the WCI to express the severity of a cold environment, meteorologists use an index derived from the WCI called the **equivalent wind chill temperature** $t_{eq,wc}$. This is the ambient temperature that would produce, in a calm wind (defined for this application as 6.4 km/h), the same WCI as the actual combination of air temperature and wind velocity:

$$t_{eq,wc} = -0.0528(\text{WCI}) + 33 \quad (86)$$

where $t_{eq,wc}$ is in °C (and frequently referred to as a **wind chill factor**), thus distinguishing it from WCI, which is given either as a cooling rate or as a plain number with no units. For velocities less than 6.4 km/h (1.8 m/s), Equation (86) does not apply, and the wind chill temperature is equal to the air temperature.

Equation (86) does not imply cooling to below ambient temperature, but recognizes that, because of wind, the cooling rate is increased as though it were occurring at the lower equivalent wind chill temperature. Wind accelerates the rate of heat loss, so that the skin surface cools more quickly toward the ambient temperature. Table 13 shows a typical wind chill chart, expressed in equivalent wind chill temperature.

Notes: Cooling power of environment expressed as an equivalent temperature under calm conditions [Equation (86)]. Winds greater than 70 km/h have little added chilling effect.

11. SPECIAL ENVIRONMENTS

Infrared Heating

Optical and thermal properties of skin must be considered in studies of the effects of infrared radiation in (1) producing changes in skin temperature and skin blood flow, and (2) evoking sensations of temperature and comfort (Hardy 1961). Although the body can be considered to have the properties of water, thermal sensation and heat transfer with the environment require a study of the skin and its interaction with visible and infrared radiation.

Figure 21 shows how skin reflectance and absorptance vary for a blackbody heat source at the temperature (in K) indicated. These curves show that darkly pigmented skin is heated more by direct radiation from a high-intensity heater at 2500 K than is lightly pigmented skin. With low-temperature, low-intensity heating equipment used for total area heating, there is minimal, if any, difference. Also, in practice, clothing minimizes differences.

Changes in skin temperature caused by high-intensity infrared radiation depend on the thermal conductivity, density, and specific heat of living skin (Lipkin and Hardy 1954). Modeling skin heating with the heat transfer theory yields a parabolic relation between exposure time and skin temperature rise for nonpenetrating radiation:

$$t_{sf} - t_{si} = \Delta t = 2J\alpha\sqrt{\theta/(\pi k\rho c_p)} \quad (87)$$

where

t_{sf} = final skin temperature, °C
t_{si} = initial skin temperature, °C
J = irradiance from source radiation temperatures, W/m²
α = skin absorptance at radiation temperatures, dimensionless
θ = time, h
k = specific thermal conductivity of tissue, W/(m·K)
ρ = density, kg/m³
c_p = specific heat, J/(kg·K)

Product $k\rho c_p$ is the physiologically important quantity that determines temperature elevation of skin or other tissue on exposure to nonpenetrating radiation. Fatty tissue, because of its relatively low specific heat, is heated more rapidly than moist skin or bone. Experimentally, $k\rho c_p$ values can be determined by plotting Δt^2 against $1.13J^2\theta$ (Figure 22). The relationship is linear, and the slopes are inversely proportional to the $k\rho c_p$ of the specimen. Comparing leather and water with body tissues suggests that thermal inertia values depend largely on tissue water content.

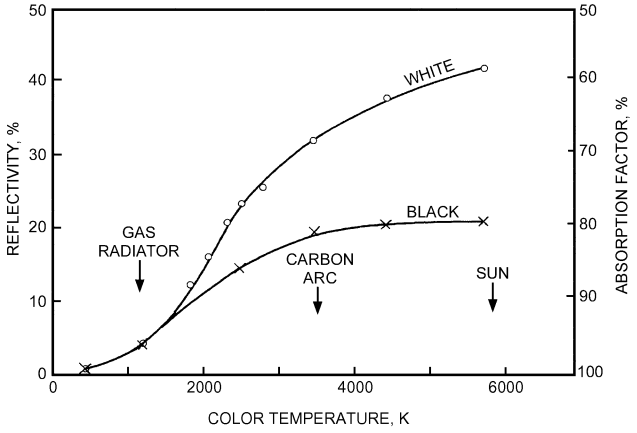

Fig. 21 Variation in Skin Reflection and Absorptivity for Blackbody Heat Sources

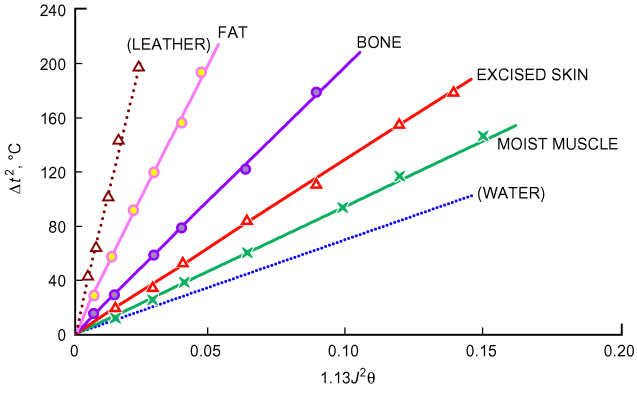

Fig. 22 Comparing Thermal Inertia of Fat, Bone, Moist Muscle, and Excised Skin to That of Leather and Water

Living tissues do not conform strictly to this simple mathematical formula. Figure 23 compares excised skin with living skin with normal blood flow, and skin with blood flow occluded. For short exposure times, the $k\rho c_p$ of normal skin is the same as that in which blood flow has been stopped; excised skin heats more rapidly because of unavoidable dehydration that occurs postmortem.

Licensed for single user. © 2021 ASHRAE, Inc.

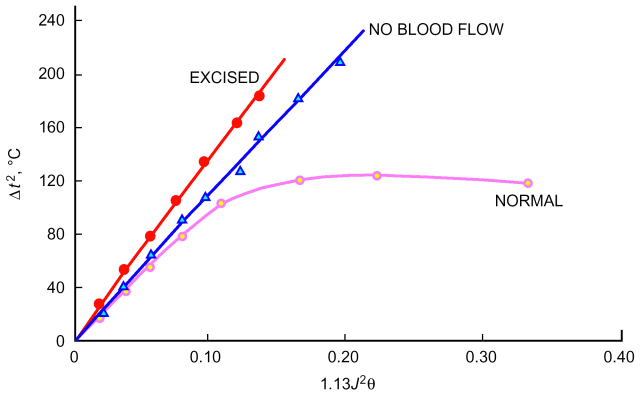

Fig. 23 Thermal Inertias of Excised, Bloodless, and Normal Living Skin

However, with longer exposure to thermal radiation, vasodilation increases blood flow, cooling the skin. For the first 20 s of irradiation, skin with normally constricted blood vessels has a $k\rho c_p$ value one-fourth that for skin with fully dilated vessels.

Skin temperature is the best single index of thermal comfort. The most rapid changes in skin temperature occur during the first 60 s of exposure to infrared radiation. During this initial period, thermal sensation and the heating rate of the skin vary with the quality of infrared radiation (color temperature in K). Because radiant heat from a gas-fired heater is absorbed at the skin surface, the same unit level of absorbed radiation during the first 60 s of exposure can cause an even warmer initial sensation than penetrating solar radiation. Skin heating curves tend to level off after a 60 s exposure (Figure 23), which means that a relative balance is quickly created between heat absorbed, heat flow to the skin surface, and heat loss to the ambient environment. Therefore, the effects of radiant heating on thermal comfort should be examined for conditions approaching thermal equilibrium.

Stolwijk and Hardy (1966) described an unclothed subject's response for a 2 h exposure to temperatures of 5 to 35°C. Nevins et al. (1966) showed a relation between ambient temperatures and thermal comfort of clothed, resting subjects. For any given uniform environmental temperature, both initial physiological response and degree of comfort can be determined for a subject at rest.

Physiological implications for radiant heating can be defined by two environmental temperatures: (1) mean radiant temperature $\bar{t}_r$ and (2) ambient air temperature t_a. For this discussion on radiant heat, assume that (1) relative humidity is less than 50%, and (2) air movement is low and constant, with an equivalent convection coefficient of 2.9 W/(m^2·K).

The equilibrium equation, describing heat exchange between skin surface at mean temperature t_{sk} and the radiant environment, is given in Equation (28), and can be transformed to give (see Table 2)

$$M' - E_{sk} - F_{cle}[h_r(t_{sk} - \bar{t}_r) + h_c(t_{sk} - t_o] = 0 \quad (88)$$

where M' is the net heat production ($M - W$) less respiratory losses.

By algebraic transformation, Equation (88) can be rewritten as

$$M' + \text{ERF} \times F_{cle} = E_{sk} + (h_r + h_c)(t_{sk} - t_a)F_{cle} \quad (89)$$

where ERF = $h_r(\bar{t}_r - t_a)$ is the effective radiant field and represents the additional radiant exchange with the body when $\bar{t}_r \neq t_a$.

The last term in Equation (89) describes heat exchange with an environment uniformly heated to temperature t_a. The term h_r, evaluated in Equation (35), is also a function of posture, for which factor A_r/A_D can vary from 0.67 for crouching to 0.73 for standing. For preliminary analysis, a useful value for h_r is 4.7 W/(m^2·K), which corresponds to a normally clothed (at 24°C) sedentary subject. Ambient air movement affects h_c, which appears only in the right-hand term of Equation (89).

Although the linear radiation coefficient h_r is used in Equations (88) and (89), the same definition of ERF follows if the fourth power radiation law is used. By this law, assuming emissivity of the body surface is unity, the ERF term in Equation (89) is

$$\text{ERF} = \sigma(A_r/A_D)[(\bar{t}_r - 273)^4 - (t_a + 273)^4]F_{cle} \quad (90)$$

where σ is the Stefan-Boltzmann constant, 5.67×10^{-8} W/(m^2·K^4).

Because $\bar{t}_r$ equals the radiation of several surfaces at different temperatures (T_1, T_2, . . . , T_j),

$$\text{ERF} = (\text{ERF})_1 + (\text{ERF})_2 + \cdots + (\text{ERF})_j \quad (91)$$

where

$\text{ERF}_j = \sigma(A_r/A_D)\alpha_j F_{m-j}(T_j^4 - T_a^4)\, F_{cle}$

α_j = absorptance of skin or clothing surface for source radiating at temperature T_j

F_{m-j} = angle factor to subject m from source j

T_a = ambient air temperature, K

ERF is the sum of the fields caused by each surface T_j [e.g., T_1 may be an infrared beam heater; T_2, a heated floor; T_3, a warm ceiling; T_4, a cold plate glass window ($T_4 < T_a$); etc.]. Only surfaces with T_j differing from T_a contribute to the ERF.

Comfort Equations for Radiant Heating

The **comfort equation for radiant heat** (Gagge et al. 1967a, 1967b) follows from definition of ERF and Equation (8):

$$t_o \text{ (for comfort)} = t_a + \text{ERF (for comfort)}/h \quad (92)$$

Thus, operative temperature for comfort is the temperature of the ambient air plus a temperature increment ERF/h, a ratio that measures the effectiveness of the incident radiant heating on occupants. Higher air movement (which increases the value of h or h_c) reduces the effectiveness of radiant heating systems. Clothing lowers t_o for comfort and for thermal neutrality.

Values for ERF and h must be determined to apply the comfort equation for radiant heating. Table 3 may be used to estimate h. One method of determining ERF is to calculate it directly from radiometric data that give (1) radiation emission spectrum of the source, (2) concentration of the beam, (3) radiation from the floor, ceiling, and windows, and (4) corresponding angle factors involved. This analytical approach is described in Chapter 55 of the 2019 *ASHRAE Handbook—HVAC Applications*.

For direct measurement, a black globe, 150 mm in diameter, can measure the radiant field ERF for comfort, by the following relation:

$$\text{ERF} = (A_r/A_D)(6.1 + 13.6\sqrt{V})(t_g - t_a) \quad (93)$$

where t_g is uncorrected globe temperature in °C and V is air movement in m/s. The average value of A_r/A_D is 0.7. For a black globe, ERF must be multiplied by α for the exposed clothing/skin surface. For a subject with 0.6 to 1.0 clo, t_o for comfort should agree numerically with t_a for comfort in Figure 5. When t_o replaces t_a in Figure 5, humidity is measured in vapor pressure rather than relative humidity, which refers only to air temperature.

Other methods may be used to measure ERF. The most accurate is by physiological means. In Equation (89), when M, $t_{sk} - t_a$, and the associated transfer coefficients are experimentally held constant,

Licensed for single user. © 2021 ASHRAE, Inc.

$$\Delta E = \Delta \text{ERF} \tag{94}$$

The variation in evaporative heat loss E (rate of mass loss) caused by changing the wattage of two T-3 infrared lamps is a measure in absolute terms of the radiant heat received by the body.

A third method uses a directional radiometer to measure ERF directly. For example, radiation absorbed at the body surface (in W/m^2) is

$$\text{ERF} = \alpha(A_i/A_D)J \tag{95}$$

where irradiance J can be measured by a directional (Hardy-type) radiometer, α is the surface absorptance effective for the source used, and A_i is the projection area of the body normal to the directional irradiance. Equation (95) can be used to calculate ERF only for the simplest geometrical arrangements. For a human subject lying supine and irradiated uniformly from above, A_i/A_D is 0.3. Figure 21 shows variance of α for human skin with blackbody temperature (in K) of the radiating source. When irradiance J is uneven and coming from many directions, as is usually the case, the previous physiological method can be used to obtain an effective A_i/A_D from the observed ΔE and $\Delta(\alpha J)$.

Personal Environmental Control (PEC) Systems

Because of the large interpersonal variability in thermal requirements, some occupants in any uniformly conditioned environment will be too warm at the same time as others are too cool. The ASHRAE 80% acceptability criterion reflects this physiological constraint. Only environments that respond to individual preferences are capable of thermally satisfying all occupants (Bauman et al. 1998). Such occupant-specific microenvironments may be conditioned with low energy input because their aggregate volume is smaller than the total space volume, and because heating or cooling the occupants themselves may be more energy efficient than space conditioning. Such designs require attention to the thermal sensitivities of different parts of the human body and to the physical properties of its microenvironment.

In warm conditions, the comfort of the head and hands dictates a person's overall discomfort; in cool conditions, the feet and hands dictate overall discomfort (Arens et al. 2006; Zhang 2003). Keeping the feet and hands warm is necessary to prevent discomfort from vasoconstriction in the limbs. However in warm conditions, the hands and wrists are important heat dissipaters, and cooling them is important. Arens et al. (2006) and Zhang (2003) suggest that a personal environmental control (PEC) system, also called **task-ambient conditioning (TAC)** or **personal ventilation (PV) systems**, that focuses directly on these body parts may offer an energy-efficient means for improving comfort in office environments.

PEC fan systems using either recirculated room air or outdoor air can provide comfort and improve perceived air quality (Amai et al. 2007; Arens et al. 2008, 2011; Dygert and Dang 2011; Melikov 2003; Russo and Khalifa 2011; Sekhar et al. 2005; Tham and Willem 2004; Yang et al. 2009, 2010; Zhang et al. 2010d). Air quality can also be improved, because fan flows above 0.3 m/s disrupt the body's thermal plume that carries pollutants upward to the breathing zone (Arens et al. 2008, 2011).

Using air movement for cooling has constraints. Strong airflow directed at the eyes might cause dry-eye discomfort and should be avoided (Melikov et al. 2011). However, a large percentage of office occupants in neutral and warm conditions prefer an increase in available air movement (Arens et al. 2009). A recent study of hemoglobin levels showed that air movement also reduces fatigue (Nishihara and Tanabe 2011; Tanabe and Nishihara 2004).

Foot heating is usually done by radiant heating or through contact with a heated surface. Efficiency of these systems depends greatly on confining the heating to the body surfaces without too much loss to the surrounding air.

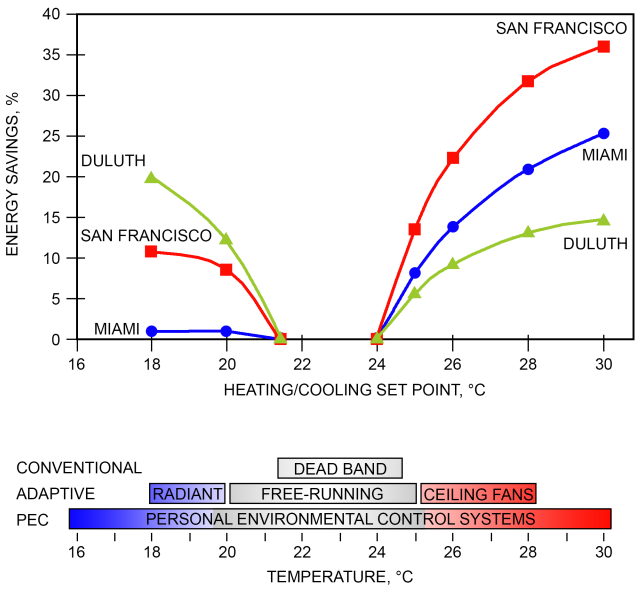

Fig. 24 Recommended Temperature Set Points for HVAC with PEC Systems and Energy Savings from Extending HVAC Temperature Set Points
[Based on Hoyt et al. (2009) and Zhang et al. (2011)]

Hands and wrists may both be heated and cooled by contact with conductive surfaces. Wrist cooling may not require actively cooled surfaces, because the skin is almost always at a higher temperature than surfaces in a normal environment.

Some researchers suggest that a PEC system can be part of an energy-saving strategy (Hoyt et al. 2009; Zhang et al. 2011) by keeping occupants comfortable while allowing the surrounding spaces to be less conditioned (Figure 24). The success of this strategy also depends on the length of time occupants are away from the PEC zone. Once steady state is reached, the change of sensations when moving from a comfortable environment to one less comfortable is much slower than the change on returning to comfortable conditions (Zhang et al. 2010a). For example, 10-min excursions climbing stairs were judged comfortable throughout, despite a 28°C stairwell temperature, whereas 15-min excursions climbing stairs became uncomfortable; occupants judged their status comfortable/acceptable within 30 s of returning to the PEC zone.

Hot and Humid Environments

Tolerance limits to high temperature vary with the ability to (1) sense temperature, (2) lose heat by regulatory sweating, and (3) move heat from the body core by blood flow to the skin surface, where cooling is the most effective. many interrelating processes are involved in heat stress (Figure 25).

Skin surface temperatures of 46°C trigger pain receptors in the skin; direct contact with metal at this temperature is painful. However, because thermal insulation of the air layer around the skin is high, much higher dry-air temperatures can be tolerated (e.g., 85°C for brief periods in a sauna). For lightly clothed subjects at rest, tolerance times of nearly 50 min have been reported at 82°C db; 33 min at 93°C; 26 min at 104°C; and 24 min at 115°C. In each case, dew points were lower than 30°C. Short exposures to these extremely hot environments are tolerable because of cooling by sweat evaporation. However, when ambient vapor pressure approaches 6.0 kPa (36°C dp, typically found on sweating skin), tolerance is drastically reduced. Temperatures of 50°C can be intolerable if the dew-point temperature is greater than 25°C, and both deep

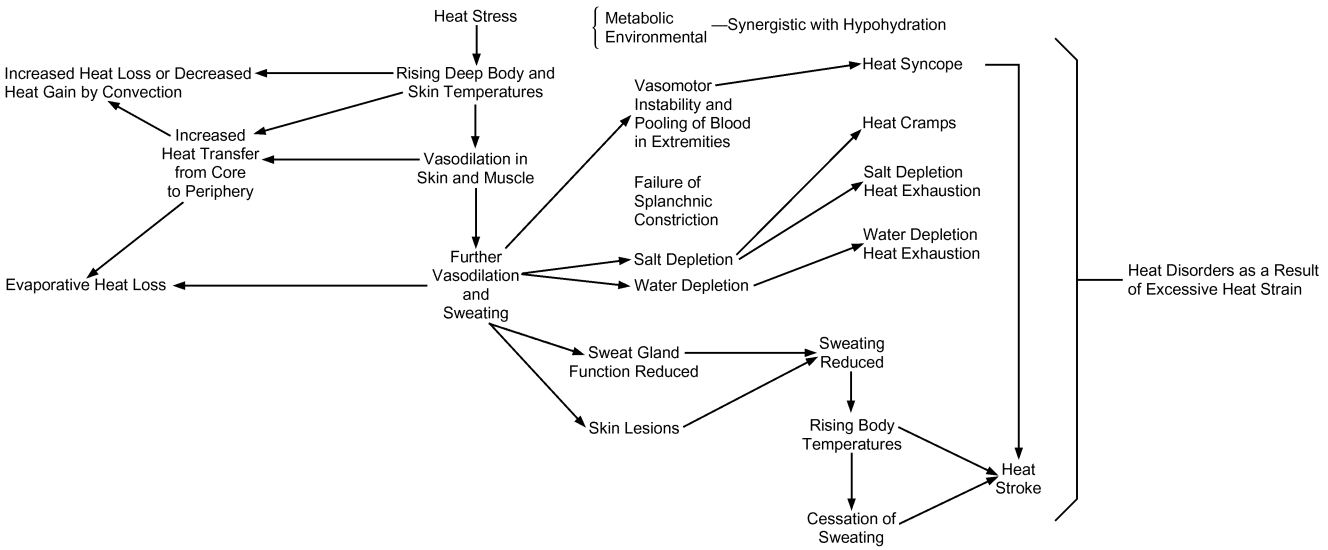

Fig. 25 Schematic Design of Heat Stress and Heat Disorders
[Modified by Buskirk (1960) from scale diagram by Belding (1967) and Leithead and Lind (1964)]

body temperature and heart rate rise within minutes (Gonzalez et al. 1978).

The rate at which and length of time a body can sweat are limited. The maximum rate of sweating for an average man is about 0.5 g/s. If all this sweat evaporates from the skin surface under conditions of low humidity and air movement, maximum cooling is about 675 W/m^2. However, because sweat rolls off the skin surface without evaporative cooling or is absorbed by or evaporated within clothing, a more typical cooling limit is 6 met (350 W/m^2), representing approximately 0.3 g/s (1 L/h) of sweating for the average man.

Thermal equilibrium is maintained by dissipation of resting heat production (1 met) plus any radiant and convective load. If the environment does not limit heat loss from the body during heavy activity, decreasing skin temperature compensates for the core temperature rise. Therefore, mean body temperature is maintained, although the gradient from core to skin is increased. Blood flow through the skin is reduced, but muscle blood flow necessary for exercise is preserved. The upper limit of skin blood flow is about 25 g/s (Burton and Bazett 1936).

Body heat storage of 335 kJ (or a rise in t_b of 1.4 K) for an average-sized man represents an average voluntary tolerance limit. Continuing work beyond this limit increases the risk of heat exhaustion. Collapse can occur at about 670 kJ of storage (2.8 K rise); few individuals can tolerate heat storage of 920 kJ (3.8 K above normal).

The cardiovascular system affects tolerance limits. In normal, healthy subjects exposed to extreme heat, heart rate and cardiac output increase in an attempt to maintain blood pressure and supply of blood to the brain. At a heart rate of about 180 bpm, the short time between contractions prevents adequate blood supply to the heart chambers. As heart rate continues to increase, cardiac output drops, causing inadequate convective blood exchange with the skin and, perhaps more important, inadequate blood supply to the brain. Victims of this heat exhaustion faint or black out. Accelerated heart rate can also result from inadequate venous return to the heart caused by blood pooling in the skin and lower extremities. In this case, cardiac output is limited because not enough blood is available to refill the heart between beats. This occurs most frequently when an overheated individual, having worked hard in the heat, suddenly stops working. The muscles no longer massage the blood back past the valves in the veins toward the heart. Dehydration compounds the problem by reducing fluid volume in the vascular system.

If core temperature t_{cr} increases above 41°C, critical hypothalamic proteins can be damaged, resulting in inappropriate vasoconstriction, cessation of sweating, increased heat production by shivering, or some combination of these. Heat stroke damage is frequently irreversible and carries a high risk of death.

Another problem, hyperventilation, occurs mainly in hot/wet conditions, when too much CO_2 is washed from the blood. This can lead to tingling sensations, skin numbness, and vasoconstriction in the brain with occasional loss of consciousness.

Because a rise in heart rate or rectal temperature is essentially linear with ambient vapor pressure above a dew point of 25°C, these two changes can measure severe heat stress. Although individual heart rate and rectal temperature responses to mild heat stress vary, severe heat stress saturates physiological regulating systems, producing uniform increases in heart rate and rectal temperature. In contrast, sweat production measures stress under milder conditions but becomes less useful under more severe stress. The maximal sweat rate compatible with body cooling varies with (1) degree of heat acclimatization, (2) duration of sweating, and (3) whether the sweat evaporates or merely saturates the skin and drips off. Total sweat rates over 2 L/h can occur in short exposures, but about 1 L/h is an average maximum sustainable level for an acclimatized man.

Figure 26 shows the decline in heart rate, rectal temperature, and skin temperature when exercising subjects are exposed to 40°C over a period of days. Acclimatization can be achieved by working in the heat for 100 min each day: 30% improvement occurs after the first day, 50% after 3 days, and 95% after 6 or 7 days. Increased sweat secretion while working in the heat can be induced by rest. Although reducing salt intake during the first few days in the heat can conserve sodium, heat cramps may result. Working regularly in the heat improves cardiovascular efficiency, sweat secretion, and sodium conservation. Once induced, heat acclimatization can be maintained by as little as one workout a week in the heat; otherwise, it diminishes slowly over a 2- to 3-week period and disappears.

Extremely Cold Environments

Human performance in extreme cold ultimately depends on maintaining thermal balance. Subjective discomfort is reported by a 70 kg man with 1.8 m^2 of body surface area when a heat debt of about 104 kJ is incurred. A heat debt of about 630 kJ is acutely

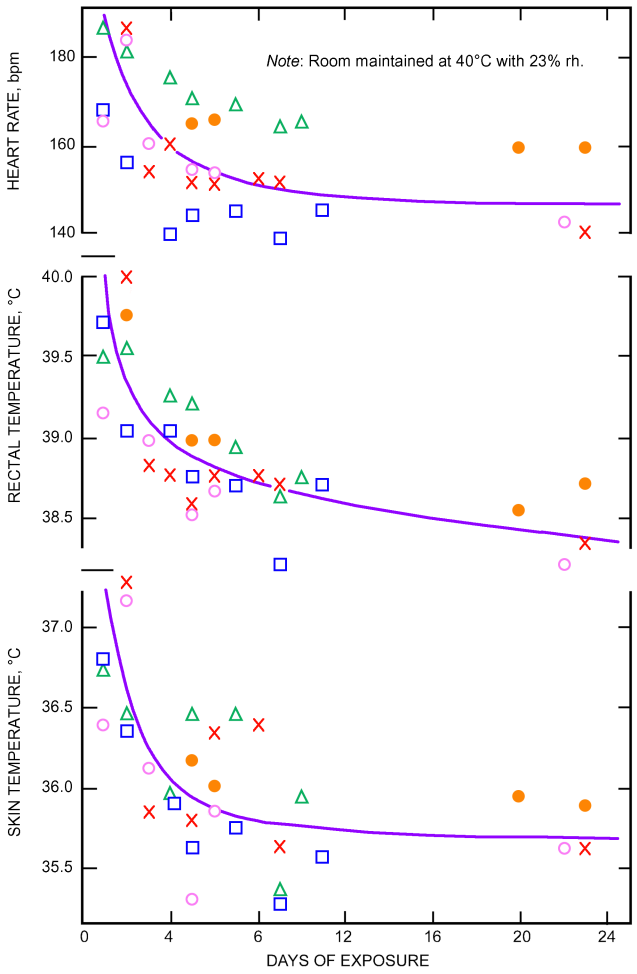

Fig. 26 Acclimatization to Heat Resulting from Daily Exposure of Five Subjects to Extremely Hot Room
(Robinson et al. 1943)

uncomfortable; this represents a drop of approximately 2.6 K (or about 7% of total heat content) in mean body temperature.

This loss can occur during 1 to 2 h of sedentary activity outdoors. A sleeping individual will wake after losing about 314 kJ, decreasing mean skin temperature by about 3 K and deep body temperature by about 0.5 K. A drop in deep body temperature (e.g., rectal temperature) below 35°C threatens a loss of body temperature regulation, and 28°C is considered critical for survival, despite recorded survival from a deep body temperature of 18°C.

Activity level also affects human performance. Subjective sensations reported by sedentary subjects at a mean skin temperature of 33.3°C are comfortable; at 31°C, uncomfortably cold; at 30°C, shivering cold; and at 29°C, extremely cold. The critical subjective tolerance limit (without numbing) for mean skin temperature appears to be about 25°C. However, during moderate to heavy activity, subjects reported the same skin temperatures as comfortable. Although mean skin temperature is significant, the temperature of the extremities is more frequently the critical factor for comfort in the cold. Consistent with this, one of the first responses to cold exposure is vasoconstriction, which reduces circulatory heat input to the hands and feet. A hand-skin temperature of 20°C causes a report of uncomfortably cold; 15°C, extremely cold; and 5°C, painful. Identical verbal responses for the foot surface occur at approximately 1.5 to 2 K warmer temperatures.

An ambient temperature of −35°C is the lower limit for useful outdoor activity, even with adequate insulative clothing. At −50°C, almost all outdoor effort becomes exceedingly difficult; even with appropriate protective equipment, only limited exposure is possible. Reported exposures of 30 min at −75°C have occurred in the Antarctic without injury.

In response to extreme heat loss, maximal heat production becomes very important. When the less-efficient vasoconstriction cannot prevent body heat loss, shivering is an automatic, more efficient defense against cold. This can be triggered by low deep body temperature, low skin temperature, rapid change of skin temperature, or some combination of all three. Shivering is usually preceded by an imperceptible increase in muscle tension and by noticeable gooseflesh produced by muscle contraction in the skin. It begins slowly in small muscle groups, initially increasing total heat production by 1.5 to 2 times resting levels. As body cooling increases, the reaction spreads to additional body segments. Ultimately violent, whole-body shivering causes maximum heat production of about 6 times resting levels, rendering the individual totally ineffective.

Given sufficient cold exposure, the body undergoes changes that indicate cold acclimatization. These physiological changes include (1) endocrine changes (e.g., sensitivity to norepinephrine), causing nonshivering heat production by metabolism of free fatty acids released from adipose tissue; (2) improved circulatory heat flow to skin, causing an overall sensation of greater comfort; and (3) improved circulatory heat flow to the extremities, reducing the risk of injury and allowing activities at what ordinarily would be severely uncomfortable temperatures in the extremities. Generally, these physiological changes are minor and are induced only by repeated extreme exposures. Nonphysiological factors, including training, experience, and selection of adequate protective clothing, are more useful and may be safer than dependence on physiological changes.

Food energy intake requirements for adequately clothed subjects in extreme cold are only slightly greater than those for subjects living and working in temperate climates. This greater requirement results from added work caused by (1) carrying the weight of heavy clothing (energy cost for heavy protective footwear may be six times that of an equivalent weight on the torso); and (2) the inefficiency of walking in snow, snowshoeing, or skiing, which can increase energy cost up to 300%.

To achieve proper protection in low temperatures, a person must either maintain high metabolic heat production by activity or reduce heat loss by controlling the body's microclimate with clothing. Other protective measures include spot radiant heating, showers of hot air for work at a fixed site, and warm-air-ventilated or electrically heated clothing. Extremities (e.g., fingers and toes) are at greater risk than the torso because, as thin cylinders, they are particularly susceptible to heat loss and difficult to insulate without increasing the surface for heat loss. Vasoconstriction can reduce circulatory heat input to extremities by over 90%.

Although there is no ideal insulating material for protective clothing, radiation-reflective materials are promising. Insulation is primarily a function of clothing thickness; the thickness of trapped air, rather than fibers used, determines insulation effectiveness.

Protection for the respiratory tract seems unnecessary in healthy individuals, even at −45°C. However, asthmatics or individuals with mild cardiovascular problems may benefit from a face mask that warms inspired air. Masks are unnecessary for protecting the face because heat to facial skin is not reduced by local vasoconstriction, as it is for hands. If wind chill is great, there is always a risk of cold injury caused by freezing of exposed skin. Using properly designed torso clothing, such as a parka with a fur-lined hood to minimize wind penetration to the face, and 10 W of auxiliary heat to each hand and foot, inactive people can tolerate −55°C with a 16 km/h wind for more than 6 h. As long as the skin temperature of fingers remains

Licensed for single user. © 2021 ASHRAE, Inc.

above 15°C, manual dexterity can be maintained and useful work performed without difficulty.

12. SYMBOLS

A = area, m^2
BFN = neutral skin blood flow, $g/(m^2 \cdot s)$
c = specific heat, $J/(kg \cdot K)$
c_{dil} = specific heat (constant) for skin blood flow
c_{sw} = proportionality constant for sweat control, 170 $W/(m^2 \cdot K)$
C = convective heat loss, W/m^2
$C + R$ = total sensible heat loss from skin, W/m^2
DISC = thermal discomfort
E = evaporative heat loss, W/m^2
ERF = effective radiant field, W/m^2
ET* = effective temperature based on 50% rh, °C
f_{cl} = clothing area factor, A_{cl}/A_D, dimensionless
F = thermal efficiency, or angle factor
h = enthalpy, kJ/kg (dry air), or heat transfer coefficient, $W/(m^2 \cdot K)$
HSI = heat stress index
i = vapor permeation efficiency, dimensionless
I = thermal resistance in clo units, clo
J = irradiance, W/m^2
k = thermal conductivity of body tissue, $W/(m \cdot K$
K = effective conductance between core and skin, $W/(m^2 \cdot K)$
K_{res} = proportionality constant, 1.43 kg/kJ
l = height, m
L = thermal load on body, W/m^2
LR = Lewis ratio, K/kPa
m = mass, kg
$\dot{m}$ = mass flow, $kg/(s \cdot m^2)$
M = metabolic heat production, W/m^2
p = water vapor pressure, kPa
PD = percent dissatisfied
PMV = predicted mean vote
PPD = predicted percent dissatisfied
q = heat flow, W/m^2
Q = volume rate, m^3/h, or volume flow rate of blood per unit surface area, $L/(h \cdot m^2)$
R = thermal resistance, $(m^2 \cdot K)/W$, or radiative heat loss from skin, W/m^2
RQ = respiratory quotient, dimensionless
S = heat storage, W/m^2
SET* = standard effective temperature, °C
SkBF = skin blood flow, $g/(m^2 \cdot s)$
t = temperature, °C
$\bar{t}_r$ = mean temperature, °C
T = absolute temperature, K
TSENS = thermal sensation
Tu = turbulence intensity, %
V = air velocity, m/s
V_{sd} = standard deviation of velocity measured with omnidirectional anemometer with 0.2 s time constant
w = skin wettedness, dimensionless
W = external work accomplished, W/m^2, or humidity ratio of air, kg (water vapor)/kg (dry air)
WBGT = wet-bulb globe temperature, °C
WCI = wind chill index, W/m^2
WGT = wet-globe temperature, °C
x_f = fabric thickness, mm

Greek

α = skin absorptance, dimensionless
ε = emissivity, dimensionless
η_{ev} = evaporative efficiency, dimensionless
θ = time, s
μ = mechanical efficiency of body = W/M, dimensionless
μ_T = mean space temperature, °C
ν = unsolicited thermal complaint rate, complaints/(h·zone area)
ρ = density, kg/m^3
ρ_{bl} = density of blood, 1.06 kg/L
σ = Stefan-Boltzmann constant = 5.67×10^{-8} $W/(m^2 \cdot K^4)$
σ_T = standard deviation of space temperature, K
$\sigma_{\dot{T}_H}, \sigma_{\dot{T}_L}$ = standard deviation of rate of change of high and low space temperature, K/h

Superscripts and Subscripts

$'$ = overall, net
a = ambient air
act = activity
b = of body tissue
B = building
b,c = lower limit for evaporative regulation zone
b,h = upper limit for evaporative regulation zone
bl = of blood
c = convection, or comfort
cc = corrected convection value
ch = between chair and body
cl = of clothed body or clothing
cle = of clothing, effective
clu,i = effective insulation of garment i
com = combined
cr = body core
cr,sk = from core to skin
D = DuBois value
db = dry bulb
dif = due to moisture diffusion through skin
dil = skin blood flow
dp = dew point
dry = sensible
e = evaporative, at surface
ec = at surface, corrected
eq,wc = equivalent wind chill
$evap$ = latent
ex = exhaled air
fg = vaporization of water
g = globe
G = covered by garment
ge = gas exchange
h = too hot
l = too cold
m = total
max = maximum
$m-j$ = from person to source j
N = of surface N
nwb = naturally ventilated wet bulb
o = operative
oc = operative comfort
oh = humid operation
out = monthly mean outside
p = at constant pressure
pcl = permeation
$p-N$ = between person and source N
pr = plane radiant
r = radiation, radiant
req = required
res = respiration
rsw = regulatory sweat
s = saturated
sf = final skin
$shiv$ = shivering
si = initial skin
sk = skin
sw = sweat
t = atmospheric, or total
tr = constriction constant for skin blood flow
wb = wet bulb
w,res = respiratory water loss

CHAPTER 10

INDOOR ENVIRONMENTAL HEALTH

BACKGROUND 10.1
Health Sciences Relevant to Indoor Environment 10.3
Hazard Recognition, Analysis, and Control 10.4
AIRBORNE CONTAMINANTS 10.4
Particles 10.5
Gaseous Contaminants 10.9
PHYSICAL AGENTS 10.16
Thermal Environment 10.16
Electrical Hazards 10.19
Mechanical Energies 10.19
Electromagnetic Radiation 10.21
Ergonomics 10.23
Outdoor Air Ventilation and Health 10.23

INDOOR environmental health comprises those aspects of human health and disease that are determined by factors in the indoor environment. It also refers to the theory and practice of assessing and controlling factors in the indoor environment that can potentially affect health. The practice of indoor environmental health requires consideration of chemical, biological, physical and ergonomic hazards, and has the goal of increasing healthy indoor environments.

Diseases are caused by genetics and exposures [biological (biotic) and/or chemical or physical (abiotic)]. Despite a huge investment in DNA research in recent decades, few diseases can be solely explained by our genes. An interaction between genes and environmental exposures is needed, and understanding indoor environmental exposures is essential in this respect. Over a 70-year lifespan in a developed region, indoor air (in homes, schools, day cares, offices, shops, etc.) constitutes around 65% of the total lifetime exposure (in mass), whereas outdoor air, air during transportation, food, and liquid makes up the rest. For more vulnerable populations, such as newborns, the elderly, and the homebound ill, indoor air in homes makes up around 80% of the exposure.

It is essential for engineers and others involved in building design and operation to understand the fundamentals of indoor environmental health because the design, operation, and maintenance of buildings and their HVAC systems significantly affect the health of building occupants. In many cases, buildings and systems can be designed and operated to reduce the exposure of occupants to potential hazards. Unfortunately, neglecting to consider indoor environmental health can lead to conditions that create or worsen those hazards and increased associated exposure.

This chapter provides general background information and introduces important concepts of hazard recognition, analysis, and control. It also presents information on specific hazards, and describes sources of exposure to each hazard, potential health effects, relevant exposure standards and guidelines, and methods to control exposure.

This chapter also includes a brief introduction to the very broad and dynamic field of indoor environmental health. Thus, descriptions of potential hazards (and especially their controls) presented do not constitute a comprehensive, state-of-the-art review. Additional detail is available on many important topics in other ASHRAE Handbook chapters, including

- Chapter 9, Thermal Comfort, of this volume
- Chapter 11, Air Contaminants, of this volume
- Chapter 12, Odors, of this volume
- Chapter 16, Ventilation and Infiltration, of this volume
- Chapter 29, Air Cleaners for Particulate Contaminants, of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*
- Chapter 32, Ventilation of the Industrial Environment, of the 2019 *ASHRAE Handbook—HVAC Applications*
- Chapter 47, Air Cleaners for Gaseous Contaminants, of the 2019 *ASHRAE Handbook—HVAC Applications*

Other important sources of information from ASHRAE include the building ventilation and related requirements in *Standards* 62.1 and 62.2, as well as *Standard* 170 for health care occupancies and the *Indoor Air Quality Guide* (ASHRAE 2009). Additional details are available from governmental and private sources, including the U.S. Department of Health and Human Services' Centers for Disease Control and Prevention, U.S. Environmental Protection Agency, Occupational Safety and Health Administration, American Conference of Governmental Industrial Hygienists, National Institute for Occupational Safety and Health, parallel institutions in other countries, and the World Health Organization.

1. BACKGROUND

Evaluation of exposure incidents and laboratory studies with humans and animals have generated reasonable consensus on safe and unsafe workplace exposures for about 1000 chemicals and particles. Consequently, many countries regulate exposures of workers to these agents. However, chemical and particle concentrations that meet occupational health criteria usually exceed levels acceptable to occupants in nonindustrial spaces such as offices, schools, and residences, where exposure times often last longer and exposures may involve mixtures of many contaminants and where those exposed comprise a less robust population (e.g., infants, the elderly, the infirm) (NAS 1981).

The generally accepted broad definition of health is that in the constitution of the World Health Organization (WHO): "Health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity."

Another definition of health, more narrowly focused on air pollution, presented by the American Thoracic Society (ATS 1999) takes into account broader, societal decision-making processes in defining what constitutes an adverse health effect of air pollution. Key points of the ATS definition of adverse effects include

- **Biomarkers, or biological indicators (e.g., in blood, exhaled air, sputum) of environmental effects.** Because few markers have yet been sufficiently validated for use in defining thresholds, not all changes in biomarkers related to air pollution should be considered adverse effects.
- **Quality of life.** Adverse effects of air pollution can range from watering, stinging eyes to cardiopulmonary symptoms, and even psychiatric conditions.
- **Physiological impact.** Physical effects of pollution can be transitory or permanent, and appear alone or accompanied by other symptoms. The ATS minimum requirement for considering pollution to have an adverse effect is reversible damage accompanied

The preparation of this chapter is assigned to the Environmental Health Committee.

Licensed for single user. © 2021 ASHRAE, Inc.

by other symptoms (reversible damage alone is not sufficient). Also, effects such as developmental damage to lungs, or exacerbation of age-related decay in function, must be considered.

- **Symptoms.** Not all increased occurrences of symptoms are considered adverse effects of air pollution: only those diminishing an individual's quality of life or changing a patient's clinical status should be considered adverse.
- **Clinical outcomes.** Detectable effects of air pollution on clinical tests should be considered adverse.
- **Mortality.** Any increase in mortality should be judged adverse.
- **Population health versus individual risk.** Any increase in the risk of an exposed population should be considered adverse, even if there is no immediate, outright illness.

Definitions of comfort vary. Comfort encompasses perception of the environment (e.g., hot/cold, humid/dry, noisy/quiet, bright/dark) and a value rating of affective implications (e.g., too hot, too cold). Rohles et al. (1989) noted that acceptability may represent a more useful concept of evaluating occupant response, because it allows progression toward a concrete goal. Acceptability is the foundation of a number of standards covering thermal comfort and acoustics, as well as odor comfort. Nevertheless, acceptability varies between climatic regions and cultures, and may change over time as expectations change.

Concern about the health effects associated with indoor air dates back several hundred years, and has increased significantly in recent decades. During the 1970s and 1980s, this attention was mainly a result of concerns about radon and lung cancer, and about increased reporting by building occupants of complaints about poor health associated with exposure to indoor air or sick building syndrome (SBS). More recently, interest has largely focused on asthma, allergies, and airway infections.

SBS encompasses a number of adverse health symptoms related to occupancy in a "sick" building or room, including mucosal irritation, fatigue, headache, and, occasionally, lower respiratory symptoms, and nausea. Large field studies (EPA 2012; Skov and Valbjorn 1987; Sundell et al. 1994) have shed light on the causes. Widespread occurrence of these symptoms prompted the World Health Organization to classify SBS symptoms (WHO 1983):

- General symptoms, such as headache, tiredness, nausea
- Mucous membrane symptoms in the nose, eyes, or throat, including coughing, sensations of dryness
- Skin symptoms: redness, itching, on upper body parts

Sick building syndrome is characterized by an absence of routine physical signs and clinical laboratory abnormalities with regard to sensory irritation and neurotoxic symptoms, while skin symptoms often can be objectively verified. Some investigations have sought to correlate SBS symptoms with reduced neurological and physiological performance. In controlled studies, SBS symptoms can reduce performance in susceptible individuals (Mølhave et al. 1986).

Building-related illnesses (BRIs) have similar symptoms, but include physical signs and abnormalities that can be more easily clinically identified (e.g., hypersensitivity illnesses, including hypersensitivity pneumonitis, humidifier fever, asthma, and allergic rhinitis).

Some illnesses associated with exposure in indoor environments are listed in Table 1.

Table 1 Selected Illnesses Related to Exposure in Buildings

Illness	Physical Examination	Laboratory Testing	Linkage	Causes/Exposures
Allergic rhinitis	Stuffy/runny nose, postnasal drip, pale or erythematous mucosa	Anterior and posterior rhinomanometry, acoustic rhinometry, nasal lavage, biopsy, rhinoscopy, immunoassay (IgE) or skin prick testing	Immunologic skin prick or immunoassay (IgE) or in vitro testing	Pollen and dust mites are common examples
Asthma	Coughing, wheezing, episodic dyspnea, wheezing on examination, chest tightness, temporal pattern at work	Spirometry peak expiratory flow diary, methacholine challenge, exhaled NO	Immunology testing: skin prick or immunoassay (IgE); physiology testing*	Pet dander, mold, environmental tobacco smoke, and dust mites are common examples
Organic dust toxic syndrome	Cough, dyspnea, chest tightness, feverishness	DLCO, TLC	Temporal pattern related to work	Gram-negative bacteria or endotoxin
Hypersensitivity pneumonitis	Cough, dyspnea, myalgia, weakness, rales, clubbing, feverishness	DLCO, FVC, TLC, CXR, lung biopsy	Immunology testing: IgG antibody to agents present, challenge testing, physiology testing (in acute forms): spirometry, DLCO	Causative agents include thermophilic actinomycetes; molds; mixed amoebae, fungi, and bacteria; avian proteins; certain metals and chemicals
Contact dermatitis	Dry skin, itching, scaling skin	Scaling, rash, eczema, biopsy	Patch testing; allergy testing	
Urticaria (hives)	Multiple swollen raised itchy areas of skin	Inspection, biopsy	Provocation testing	Skin irritation, foods, heat/cold, direct pressure, sunlight, drugs
Eye irritation	Eye itching, irritation, dryness	Tear-film break-up time, conjunctival staining (fluorescein)	Temporal pattern	VOCs and particulate matter are common examples
Nasal irritation	Stuffy, congested nose, rhinitis	Acoustic rhinometry, posterior and anterior rhinomanometry, nasal lavage, nasal biopsy	Temporal pattern	VOCs and particulate matter are common examples
Central nervous system symptoms	Headache, fatigue, irritability, difficulty concentrating	Neuropsychological testing	Temporal pattern (epidemiology)	Chemical compounds, noise, lighting, work stress, and carbon monoxide are common examples
Legionnaires' disease, Aspergillosis, *Pseudomonas* infection	Pneumonia, high fever, organ dysfunction	Environmental surveillance (water system monitoring), *Legionella pneumophila* identification from patient	Organism isolated from patient and source; immunology testing	*Legionella* (and other microorganism)-contaminated aerosols from water sources
Pontiac fever	Non-pneumonic flulike illness	Environmental surveillance (water system monitoring)		Range of microorganisms, chemicals

*(1) 10% decrement in FEV_1 across workday,
(2) peak flow changes suggestive of work relatedness
(3) methacholine reactivity resolving after six weeks away from exposure

DLCO = single breath carbon monoxide diffusing capacity
FVC = forced vital capacity
TLC = total lung capacity

CXR = chest X-ray
IgE = immunoassay
IgG = class G immunoglobulins
FEV_1 = forced expiratory volume in the first second

1.1 HEALTH SCIENCES RELEVANT TO INDOOR ENVIRONMENT

The study of health effects in indoor environments involves a number of scientific disciplines. A few are briefly described here to further the engineer's understanding of which health sciences may be applicable to a given environmental health problem.

Epidemiology and Biostatistics

Epidemiology studies the causes, distribution, and control of disease in a population. It represents the application of quantitative methods to evaluate health-related events and effects. Epidemiology is traditionally subdivided into observational and analytical components; the focus may be descriptive, or may attempt to identify causal relationships. Some classical criteria for determining causal relationships in epidemiology are consistency, temporality, plausibility, specificity, strength of association, and dose/response (Hill 1965).

Observational epidemiology studies are generally performed with a defined group of interest because of a specific exposure or risk factor. A control group is selected on the basis of similar criteria, but without the exposure or risk factor present. A prospective study (cohort study) consists of observations of a specific group over a long time.

Examples of epidemiological investigations are cross-sectional, experimental, and case-control studies. Observations conducted at one point in time are considered cross-sectional studies. In experimental studies, individuals are selectively exposed to a specific agent or condition. These studies are performed with the consent of the participants unless the condition is part of the usual working condition and it is known to be harmless. Control groups must be observed in parallel. Case-control studies are conducted by identifying individuals with the condition of interest and comparing factors of interest in individuals without that condition.

Industrial, Occupational, and Environmental Medicine or Hygiene

Industrial or occupational hygiene is about anticipating, recognizing, evaluating, controlling, and preventing conditions that may lead to illness or injury, or affect the well-being of workers, consumers, and/or communities. Important aspects include identifying hazardous exposures and physical stressors, determining methods for collecting and analyzing contaminant samples, evaluating measurement results, and developing suitable control measures. Occupational hygienists work closely with toxicologists for understanding chemical hazards, physicists for physical hazards (e.g., ionizing radiation), and physicians and microbiologists for biological hazards.

Microbiology

Buildings are more than inanimate physical entities, masses of inert material that remain relatively stable over time. The building and its occupants, contents, and surroundings constitute a dynamic tetrad in which all elements affect each other. In fact, a building is a dynamic combination of physical, chemical, and biological dimensions. Buildings can be described and understood as complex systems. Some new approaches, based on the frameworks, tools, and methods used by ecologists to understand ecosystems, can help engineers understand the processes and microbes continually occurring indoors and how they affect the building's inhabitants, durability, and function (Bassler 2009; Humphries 2012).

Building scientists need to understand the complex and bidirectional relationship between the physical/chemical parameters of a building and the microbiology of that environment. Attempting to control a single parameter (e.g., temperature) to regulate the growth of a single microbe (e.g., mold), for example, does not address the complexity of the system.

Microbiologists must recognize the importance of understanding all of the environmental variables that are present in a given habitat. Simply collecting microbes from surfaces or materials in a structure is not enough to understand the organisms' behavior and relationships in the context of the building. Collecting appropriate information about the building (**metadata**) such as air turnover rates and material composition is essential to understanding the microbial communities that live inside it. Microbiologists must also be ever mindful of the need to distinguish between the occurrence of a microbe and the activity (metabolome) of a microbe or microbial community.

Culture-independent (genetic) methods of identifying microorganisms in microbiology are rapidly changing our understanding of the occurrence and nature of microbes in indoor environments [see Microbiology of the Built Environment network (www.microbe.net)]. These methods have increased tenfold the number of known bacteria over the past decade. Efforts to better understand the relationship between the indoor environment and its microbial ecology are yielding new knowledge about the complexity of the indoor environment as an ecosystem (Corsi et al. 2012).

Viruses require living cells for replication, so abiotic building components, strictly speaking, do not serve as a source of viruses. Viruses in buildings come from the building's occupants. Building components or systems can provide surfaces that facilitate transmission (e.g., doorknobs), and some viruses can become airborne. A substantial body of literature compares airborne and other routes of transmission; from a building design and operations standpoint, though, avoid generalizations because transmission routes are not the same for all viruses.

Empirical data (Lowen et al. 2007) demonstrate that some airborne viruses (e.g., influenza) are inactivated more quickly at high humidity, and that low humidity rapidly reduces the size of respiratory droplets, thereby prolonging time aloft. Maintaining humidity in the range deemed comfortable to a majority of occupants reduces these effects that favor influenza transmission.

Much of the literature on fungi focuses on temperature and moisture, with some emphasis on moisture and nutrient availability, although there is sufficient nutrient content on most indoor surfaces: fungi can grow even on what appears to be clean glass. There is less literature on the factors determining bacterial species and survival indoors, in spite of the growing interest in the hygiene hypothesis and humans' intimate relationships with both beneficial and harmful bacteria (e.g., probiotics). See Flanigan et al. (2001) for details.

Moisture on many surfaces supports the life, reproduction, and evolution of microorganisms. The microorganisms themselves produce chemicals, some of which can alter the pH of the surface and subsequent surface chemistry. Many additional microbes arrive on human skin, which sheds on a regular basis. Skin cells and the oils and other chemicals in and on them, as well the bacteria living on them, end up on the floor, furniture, and even the walls and windows.

When bacteria colonize stable surfaces, they often form complex communities. The structure and composition of these communities depend not only on the organisms present, but also on the conditions surrounding them: the moisture, chemicals, and other particles present on the surface or in the air nearby. Some of these communities may even develop into **biofilms**, which are very stable communities that are resistant to many antimicrobial compounds and can shelter pathogenic microbes. Bacterial communities sense the presence of other bacteria, and when they are enough of them to collectively affect their host, they all excrete chemicals that collectively affect the host and, in the case of human hosts, can make the bacteria more infectious (Bassler 2009).

Toxicology

Toxicology studies the influence of chemicals, particles, ultrafine particles, and bioaerosols on health. All chemical substances

Licensed for single user. © 2021 ASHRAE, Inc.

may function as toxins, but low concentrations prevent many, but not all, of them from being harmful. Defining which component of the structure of a chemical predicts the harmful effect is of fundamental importance in toxicology. A second issue is defining the dose/response relationships of a chemical and the exposed population. Dose may refer to delivered dose (exposure presented to the target tissue) or absorbed dose (the dose actually absorbed by the body and available for metabolism). For many substances, the time of exposure may be most important: low-level exposure during a specific week during pregnancy, for instance, may be critical, whereas higher doses later may have less of an effect.

Because permission to conduct exposure of human subjects in experimental conditions is difficult to obtain, most toxicological literature is based on animal studies. Isolated animal systems (e.g., homogenized rat livers, purified enzyme systems, other isolated living tissues) are used to study the effects of chemicals, but extrapolation between dose level effects from animals to humans is problematic.

1.2 HAZARD RECOGNITION, ANALYSIS, AND CONTROL

Hazard recognition and analysis are conducted to determine the presence of hazardous materials or conditions as sources of potential problems. Research, inspection, and analysis determine how a particular hazard affects health. Exposure assessment, an element of hazard recognition, relies on qualitative, semiquantitative, or quantitative approaches. In many situations, air sampling can determine whether a hazardous material is present. An appropriate sampling strategy must be used to ensure validity of collected samples, determining worst-case (for compliance) or usual (average) exposures. Air sampling can be conducted to determine **time-weighted average (TWA)** exposures, which cover a defined period of time, or **short-term exposures**, which determine the magnitude of exposures to materials that are acutely hazardous. Samples may be collected for a single substance or a multicomponent mixture. Hazard analysis also characterizes the potential skin absorption or ingestion hazards of an indoor environment. Analyses of bulk material samples and surface wipe samples are also used to determine whether hazardous conditions exist. Physical agent characterization may require direct-reading sampling methods. After collection and analysis, the results must be interpreted and an appropriate control strategy developed to control, reduce, or eliminate the hazard.

A main problem today is identifying which hazards, and particularly which chemical compounds, to study, although chemicals mimicking hormones (often female hormones) are increasingly of interest.

Hazards are generally grouped into one of the following four classes of environmental stressors:

- **Chemical hazards.** Routes of exposure to airborne chemicals are inhalation (aspiration), dermal (skin) contact, dermal absorption, and ingestion. The degree of risk from exposure depends on the nature and potency of the toxic effects; the endocrine effects; susceptibility of the person exposed; and timing, magnitude, and/or duration of exposure. Airborne contaminants are very important because of their ease of dispersal from sources and the risk of exposure through the lungs or skin. Airborne chemical hazards can be gaseous (vapors or gases) or particulate (e.g., dusts, fumes, mists, aerosols, fibers). Some chemicals, such as semivolatile organic compounds (SVOCs), are both gaseous and particulate. For more information, see Chapter 11.
- **Biological hazards.** Bacteria, viruses, fungi, and other living or nonliving organisms that can cause acute and chronic illness in building occupants are classified as biological hazards in indoor environments. Routes of exposure are inhalation, dermal (skin) contact, and ingestion. The degree of risk from exposure depends on the nature and potency of the biological hazard, susceptibility of the person exposed, and magnitude and duration of exposure.
- **Physical hazards.** These include excessive levels of ionizing and nonionizing electromagnetic radiation, noise, vibration, illumination, temperature, and force.
- **Ergonomic hazards.** Tasks that involve repetitive motions, require excessive force, or must be carried out in awkward postures can damage muscles, nerves, and joints.

Hazard Control

Strategies for controlling exposures in the indoor environment include substitution (removal of the hazardous substance), isolation, disinfection, dilution ventilation, and air cleaning. Not all measures may be applicable to all types of hazards, but all hazards can be controlled by using one of them. Personal protective equipment and engineering, work practice, and administrative controls are used to apply these methods. Source removal or substitution, customarily the most effective measure, is not always feasible. Engineering controls (e.g., ventilation, air cleaning) may be effective for a range of hazards. Local exhaust ventilation is more effective for controlling point-source contaminants than is general dilution ventilation.

Hazard Analysis and Control Processes. The goal of hazard analysis and control processes is to prevent harm to people from hazards associated with buildings. Quantitative hazard analysis and control processes are practical and cost-effective. Preventing disease from hazards requires facility managers and owners to answer three simple, site-specific questions:

- What is the hazard?
- How can it be prevented from harming people?
- How can it be verified that the hazard has been prevented from harming people?

Seven principles comprise effective hazard analysis and control:

- Use process flow diagrams to perform systematic hazard analysis.
- Identify critical control points (process steps at which the hazard can be eliminated or prevented from harming people).
- Establish hazard control critical limits at each critical control point.
- Establish a hazard control monitoring plan for critical limits at critical control points.
- Establish hazard control corrective actions for each critical limit.
- Establish procedures to document all activities and results.
- Establish procedures to confirm that the plan (1) actually works under operating conditions (**validation**), (2) is implemented properly (**verification**), and (3) is periodically reassessed.

2. AIRBORNE CONTAMINANTS

Many airborne contaminants cause problems in both industrial and nonindustrial indoor environments. These include biological and nonbiological particles [e.g., synthetic vitreous fibers, asbestos, environmental tobacco smoke (ETS), combustion nuclei, dust (including human skin scales)], bioaerosols, and chemical gases and vapors. Airborne contaminants may enter the building from the outdoors or be released indoors by processes, building materials, furnishings, equipment, or occupant activities. In industrial environments, airborne contaminants are usually associated with the type of process that occurs in a specific setting, and exposures may be determined relatively easily by air sampling. Airborne contaminants in nonindustrial environments may result from emissions and/or shedding of building materials and systems; originate in outdoor air; or result from building operating and maintenance programs, procedures, or conditions. In general, compared to industrial settings, nonindustrial environments include many more contaminants with the potential to contribute to health-related problems. These contaminants are usually present in lower concentrations and often are more difficult to

Licensed for single user. © 2021 ASHRAE, Inc.

identify. More information on contaminant types, characteristics, typical levels, and measurement methods is presented in Chapter 11.

2.1 PARTICLES

Particulate matter can be solid or liquid; typical examples include dust, smoke, fumes, and mists. **Dusts** are particles of a size and density that will settle; their behavior is affected mostly by gravity. **Smoke**, **fumes**, and **mists** contain mixtures of overlapping particle sizes, many in the smaller ranges (<~0.1 μm) where gravity is less important than temperature, particle charge, and other factors in determining how long particles remain aloft.

Fibers are solid particles with length several times greater than their diameter, such as asbestos, manufactured mineral fibers, synthetic vitreous fibers, and refractory ceramic fibers. Bioaerosols of concern to human health range from 0.5 to 30 μm in diameter, but generally bacterial and fungal aerosols range from 2 to 8 μm in diameter because of agglomeration or rafting of cells or spores (Lighthart 1994).

Units of Measurement. The quantity of particles in the air is frequently reported as the mass concentration or count concentration in a given volume of air. Mass concentration units are milligrams per cubic metre of air sampled (mg/m^3) or micrograms per cubic metre of air sampled (μg/m^3). For conversion, 1 mg/m^3 = 1000 μg/m^3. Mass units are widely used in industrial environments because these units are used to express occupational exposure limits.

Count concentration units are usually expressed as counts per cubic foot, cubic centimetre (cc), or cubic metre, and are specified for a given range of particle diameter. Count concentration measurements are generally used in environments such as office buildings and industrial cleanrooms.

General Health Effects of Exposure. Health effects of airborne particulate matter depend on several factors, including particle dimension, durability, dose, and toxicity of materials in the particle. Respirable particles vary in size from <1 to 10 μm (Alpaugh and Hogan 1988). Methods for measuring airborne particles are discussed in Chapter 11. **Durability** (how long the particle can exist in the biological system before it dissolves or is transported from the system) and **dose** (amount of exposure encountered by the worker) both affect relative toxicity. In some instances, very low exposures can cause adverse health effects (hazardous exposures), and in others, seemingly high exposures may not cause any adverse health effects (nuisance exposures).

Safety and health professionals are primarily concerned with particles smaller than 2 μm. Particles larger than 8 to 10 μm in aerodynamic diameter are primarily separated and retained by the upper respiratory tract. Intermediate sizes are deposited mainly in the conducting airways of the lungs, from which they are rapidly cleared and swallowed or coughed out. About 50% or less of the particles in inhaled air settle in the respiratory tract. Submicron particles penetrate deeper into the lungs, but many do not deposit and are exhaled. Nanoparticles (<100 nm diameter) can enter the blood and be transported to the brain or other organs (Mühlfeld et al. 2008).

Industrial Environments

Exposures and Exposure Sources. In industrial environments, airborne particles are generated by work-related activities (e.g., adding batch ingredients for a manufacturing process, applying asphalt in a roofing operation, drilling an ore deposit in preparation for blasting). The engineer must recognize sources of particle generation to appropriately address exposure concerns. Dusts are generated by handling, crushing, or grinding, and may become airborne during generation or handling. Any industrial process that produces dust fine enough (about 10 μm) to remain in the air long enough to be inhaled or ingested should be regarded as potentially hazardous. In determining worker exposure, the nature of particles released by the activity, local air movement caused by makeup air and exhaust, and worker procedures should be assessed for a complete evaluation (Burton 2000).

Health Effects of Industrial Exposures. Pneumoconiosis is a fibrous hardening of the lungs caused by irritation from inhaling dust in industrial settings. The most commonly known pneumoconioses are asbestosis, silicosis, and coal worker's pneumoconiosis.

Asbestosis results from inhalation of asbestos fibers found in the work environment. The U.S. Department of Health and Human Services (ATSDR 2001) characterizes the toxicological and adverse health effects of asbestos and indicates that asbestos-induced respiratory disease can generally take 10 to 20 years to develop, although there is evidence that early cases of asbestosis can develop in five to six years when fiber concentrations are very high. Asbestos fibers cause fibrosis (scarring) of lung tissue, which clinically manifests itself as dyspnea (shortness of breath) and a nonproductive, irritating cough. Asbestos fiber is both dimensionally respirable and durable in the respiratory system.

Silicosis, probably the most common of all industrial occupational lung diseases, is caused by inhalation of silica dust. Workers with silicosis usually are asymptomatic, even in the early stages of massive fibrosis (Leathart 1972). It is not considered a problem in nonindustrial indoor environments.

Coal worker's pneumoconiosis (**CWP**, also known as "black lung") results from inhalation of dust generated in coal-mining operations. The dust is composed of a combination of carbon and varying percentages of silica (usually <10%) (Alpaugh and Hogan 1988). Because of the confined underground work environment, exposures can be very high at times, thus creating very high doses. Data show that workers may develop CWP at exposures below the current dust standard of 1 mg/m^3.

Exposure Standards and Criteria. In the United States, the Occupational Safety and Health Administration (OSHA) has established permissible exposure limits (PELs) for many airborne particles. PELs are published in the Code of Federal Regulations (29CFR1910.1000, 29CFR1926.1101) under the authority of the Department of Labor. Table 2 lists PELs for several common workplace particles.

Exposure Control Strategies. Particulate or dust control strategies include source elimination or enclosure, local exhaust, general dilution ventilation, wetting, filtration, and use of personal protective devices such as respirators.

The most effective way to control exposures to particles is to totally eliminate them from the work environment. The best dust control method is total enclosure of the dust-producing process, with negative pressure maintained inside the entire enclosure by exhaust ventilation (Alpaugh and Hogan 1988).

Local exhaust ventilation as an exposure control strategy is most frequently used where particles are generated either in large volumes or with high velocities (e.g., lathe and grinding operations). High-velocity air movement captures the particles and removes them from the work environment.

Table 2 OSHA Permissible Exposure Limits (PELs) for Particles[a]

Substance	CAS[b] #	PEL
Cadmium	7440-43-9	0.005 mg/m^3
Manganese fume	7439-96-5	1.0 mg/m^3
Plaster of Paris	Nuisance	10.0 mg/m^3
Emery	Nuisance	10.0 mg/m^3
Grain dust	Nuisance	10.0 mg/m^3
Crystalline silica (as quartz)	14808-60-7	0.1 mg/m^3
Asbestos	1332-21-4	0.1 fibers/cm^3
Total dust	Nuisance	15.0 mg/m^3

Data from CFR (29CFR1910.1000, 29CFR1926.1101).

General dilution ventilation in the work environment reduces particulate exposure. This type of ventilation is used when particulate sources are numerous and widely distributed over a large area. This strategy is often the least effective means of control, and may be very costly if conditioned (warm or cold) air is exhausted and unconditioned air is introduced without benefit of air-side energy recovery. Ventilation and local exhaust for industrial environments are discussed more thoroughly in Chapters 31 and 32 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Filtration can be an effective control strategy and may be less expensive than general ventilation, although increased pressure drop across a filter can add to variable fan power requirements, and maintenance adds to system operating cost.

Using personal protective equipment (e.g., a respirator) is appropriate as a primary control during intermittent maintenance or cleaning activities when other controls are not feasible. Respirators can also supplement good engineering and work practice controls to increase employee protection and comfort (Alpaugh and Hogan 1988). Consultation with an industrial hygienist or other qualified health professional is needed to ensure proper selection, fit, and use of respirators.

Synthetic Vitreous Fibers

Exposures and Exposure Sources. Fibers are defined as slender, elongated structures with substantially parallel sides (as distinguished from a dust, which is more spherical). Synthetic vitreous fibers (SVFs) are inorganic fibrous materials such as glass wool, mineral wool (also known as rock and slag wool), textile glass fibers, and refractory ceramic fibers. These fibers are used primarily in thermal and acoustical insulation products, but are also used for filtration, fireproofing, and other applications. Human exposure to SVFs occurs mostly during manufacture, fabrication and installation, and demolition of those products, because the installed products do not result in airborne fiber levels that could produce significant consumer exposure. Simultaneous exposure to other dusts (e.g., asbestos during manufacture, demolition products and bioaerosols during demolition) is also important.

Health Effects of Exposure. Possible effects of SVFs on health include the following.

Cancer. In October 2001, an international review by the International Agency for Research on Cancer (IARC) reevaluated the 1988 IARC assessment of SVFs and insulation glass wool and rock wool. This resulted in a downgrading of the classification of these fibers from Group 2B (possible carcinogen) to Group 3 (not classifiable as to the carcinogenicity in humans). IARC noted specifically that "Epidemiologic studies published during the 15 years since the previous IARC *Monograph*'s review of these fibers in 1988 provide no evidence of increased risks of lung cancer or mesothelioma (cancer of the lining of the body cavities) from occupational exposures during manufacture of these materials, and inadequate evidence of any overall cancer risk." IARC retained the Group 2B classification for special-purpose glass fibers and refractory ceramic fibers, but its review indicated that many of the previous studies need to be updated and reevaluated, because they did not include the National Toxicology Program's Report on Carcinogens and the State of California's listing of substances known to cause cancer.

Dermatitis. SVFs may cause an irritant contact dermatitis with dermal contact and embedding in the skin, or local inflammation of the conjunctiva when fibers contact the eye. Resin binders sometimes used to tie fibers together have, on rare occasions, been associated with allergic contact dermatitis.

Exposure Standards and Criteria. OSHA has not adopted specific occupational exposure standards for SVFs. A voluntary workplace health and safety program has been established with fibrous glass and rock and slag wool insulation industries under OSHA oversight. This Health and Safety Partnership Program established an 8 h, time-weighted average permissible exposure limit of 1 fiber per cubic centimetre for respirable SVFs.

Exposure Control Strategies. As with other particles, SVF exposure control strategies include engineering controls, work practices, and use of personal protective devices. Appropriate intervention strategies focus on source control.

Combustion Nuclei

Exposures and Sources. Combustion products include water vapor, carbon dioxide, heat, oxides of carbon and nitrogen, and combustion nuclei. Combustion nuclei, defined in this chapter as particulate products of combustion, can be hazardous in many situations. They may contain potential carcinogens such as polycyclic aromatic hydrocarbons (PAHs).

Polycyclic aromatic compounds (PACs) are the nitrogen-, sulfur-, and oxygen-heterocyclic analogs of PAHs and other related PAH derivatives. Depending on their relative molecular mass and vapor pressure, PACs are distributed between vapor and particle phases. In general, combustion particles are smaller (0.01 to 4 μm) than mechanically generated dusts.

Typical sources of combustion nuclei are tobacco smoke, fossil-fuel-based heating devices (e.g., unvented space heaters and gas ranges), and flue gas from improperly vented gas- or oil-fired furnaces and wood-burning fireplaces or stoves. Infiltration of outdoor combustion contaminants can also be a significant source of these contaminants in indoor air. Therefore, combustion nuclei are important in both industrial and nonindustrial settings.

Exposure Standards and Criteria. OSHA established exposure limits for several carcinogens categorized as combustion nuclei [i.e., benzo(a)pyrene, cadmium, nickel, benzene, *n*-nitrosodimethylamine]. These limits are established for industrial work environments and are not directly applicable to general indoor air situations. Underlying atherosclerotic heart disease may be exacerbated by carbon monoxide (CO) exposures.

Exposure Control Strategies. Exposure control strategies for combustion nuclei are similar in many ways to those for other particles. For combustion nuclei derived from space heating, air contamination can be avoided by proper installation and venting of equipment to ensure that these contaminants cannot enter the work or personal environment. Proper equipment maintenance is also essential to minimize exposures to combustion nuclei.

Particles in Nonindustrial Environments

Exposures and Sources. In the nonindustrial indoor environment, particle concentrations are greatly affected by the outdoor environment. Diesel engines emit large quantities of fine particulate matter. Indoor particle sources may include cleaning, resuspension of particles from carpets and other surfaces, construction and renovation debris, paper dust, deteriorated insulation, office equipment, and combustion processes (including cooking stoves, fires, and environmental tobacco smoke).

Although **asbestos** is commonly found in buildings constructed before the 1970s, it generally does not represent a respiratory hazard except to individuals who actively disturb it during maintenance and construction.

An important source of particulates, **environmental tobacco smoke (ETS)** from cigarettes consists of exhaled mainstream smoke from the smoker and, with conventional cigarettes, the sidestream smoke emitted from the smoldering tobacco. Approximately 70 to 90% of ETS results from sidestream smoke, which has a chemical composition somewhat different from mainstream smoke. More than 4700 compounds have been identified in laboratory-based studies, including known human toxic and carcinogenic compounds such as carbon monoxide, ammonia, formaldehyde, nicotine, tobacco-specific nitrosamines, benzo(a)pyrene, benzene, cadmium, nickel, and aromatic amines. Many of these constituents

Licensed for single user. © 2021 ASHRAE, Inc.

are more concentrated in sidestream smoke than in mainstream smoke (Glantz and Parmley 1991). In studies conducted in residences and office buildings with tobacco smoking permitted, ETS was a substantial source of many gaseous and particulate PACs (Offermann et al. 1991).

Increased use of electronic cigarettes (e-cigarettes or e-cigs) and vaping has generated a new potential concern for indoor air quality. Data are still limited on potential exposures and human health risks posed by the use of e-cigarettes indoors, especially among bystanders from secondhand and third-hand exposures (AIHA 2014). Although the literature generally supports findings that e-cigarette emissions and exposure risks are much less harmful than tobacco smoke (AIHA 2014), emissions from these devices are not contaminant free. Nicotine is present in most forms of e-cigarettes, but the concentration can vary greatly and has also been found in some products identified as not containing nicotine (Burstyn 2013; Czogala et al. 2013; FDA 2009; Villa et al. 2012). Propylene glycol and vegetable glycerin are used as delivery vehicles for nicotine and various flavoring ingredients, which can break down into acrolein, formaldehyde, and acetaldehyde in the vapor (Geiss et al. 2014; Goniewicz et al. 2013; Lauterbach et al. 2012; Uchiyama et al. 2013). Flavorings used in e-cigarettes are typically considered safe for food or ingestion, but the health effects of inhaling them as vapors have not thoroughly been evaluated (AIHA 2014; Offerman 2014). Characterizing the differences in exposure from traditional cigarettes and from e-cigarettes is an active area of research.

Health Effects of Exposure. The health effects of exposure to combustion nuclei depend on many factors, including concentration, toxicity, and individual susceptibility or sensitivity to the particular substance. Combustion-generated PACs include many PAHs and nitro-PAHs that have been shown to be carcinogenic in animals (NAS 1983). Other PAHs are biologically active as tumor promoters and/or cocarcinogens. Mumford et al. (1987) reported high exposures to PAH and aza-arenes for a population in China with very high lung cancer rates.

According to the U.S. EPA (2005) fine particulate matter (particles less than 2.5 μm in diameter, or $PM_{2.5}$) is associated with lung disease, asthma, and other respiratory problems. Short-term exposure may cause shortness of breath, eye and lung irritation, nausea, light-headedness, and possible allergy aggravations.

$PM_{2.5}$ has been calculated to have the highest impact on health of studied chronic air pollutants inhaled in residences. The metric used was the disability-adjusted life years (DALYs). DALYs are a measure of the morbidity (disability) and mortality (death) caused by exposure to contaminants or other risks. $PM_{2.5}$ accounts for nearly 90% of the DALYs lost through chronic air pollutants inhaled in residences. Additional contaminants in descending importance ranked by DALYs are secondhand smoke (SHS), radon (for smokers), formaldehyde (a major source is composite wood products), and acrolein (a major source is cooking fats) (Logue et al. 2011, 2012). This type of analysis provides a rationale as well as a value that can be monetized to guide practitioners and researchers in determining which indoor contaminants are most important for control. From this analysis, $PM_{2.5}$ is clearly the obvious first target in indoor air quality: it is the dominant contaminant of concern in most residences, and one of the easiest and least expensive to control (primarily with filtration with higher-efficiency filters).

ETS has been shown to be causally associated with lung cancer in adults and respiratory infections, asthma exacerbations, middle ear effusion (DHHS 1986; NRC 1986), and low birth mass (Martin and Bracken 1986). The U.S. Environmental Protection Agency classifies ETS as a known human carcinogen (EPA 1992). Health effects can also include heart disease, headache, and irritation. ETS is also a cause of sensory irritation and annoyance (odors and eye irritation).

Table 3 Primary and Secondary Standards for Particle Pollution

	Time Span	Primary	Secondary	Notes
$PM_{2.5}$	Annual	12 μg/m³	15 μg/m³	Annual mean, averaged over three years.
	24 h	35 μg/m³		98th percentile, averaged over three years.
PM_{10}	24 h	150 μg/m³		Not to be exceeded more than once per year on average over three years.

Exposure Standards. There are no established exposure guidelines for particles in nonindustrial indoor environments. The EPA's National Ambient Air Quality standard (NAAQS) established primary and secondary standards for particle pollution. **Primary standards** provide public health protection, including protecting the health of sensitive populations such as asthmatics, children, and the elderly. **Secondary standards** provide public welfare protection, including protection against decreased visibility and damage to animals, crops, vegetation, and buildings. Table 3 gives information on primary and secondary standards for $PM_{2.5}$ and PM_{10}.

Exposure Control Strategies. Particulate or dust control strategies for the nonindustrial environment include source elimination or reduction, good housekeeping, general dilution ventilation, and upgraded filtration. In general, source control is preferred. Combustion appliances must be properly vented and maintained. If a dust problem exists, identify the type of dust to develop an appropriate intervention strategy. Damp dusting and high-efficiency vacuum cleaners may be considered. Building spaces under construction or renovation should be properly isolated from occupied spaces to limit transport of dust and other contaminants. Minimizing idling of diesel-powered vehicles near buildings can reduce entry of fine particulate matter.

Control of ETS has been accomplished primarily through regulatory mandates on the practice of tobacco smoking indoors. Most U.S. states and E.U. member states have passed laws to control tobacco smoking in at least some public places, including public buildings, restaurants, and workplaces, and the FAA (2000) has prohibited smoking on all flights to and from the United States, as have many airlines throughout the world. Where tobacco smoking is permitted, appropriate local and general dilution ventilation can be used for control; however, the efficacy of ventilation is unproven (Repace 1984). Some studies indicate that extremely high ventilation rates may be needed to dilute secondhand smoke to minimal risk levels (Repace and Lowrey 1985, 1993).

Bioaerosols

Bioaerosols are airborne biological particles derived from viruses, bacteria, fungi, protozoa, algae, mites, plants, insects, and their by-products, fragments, and cell mass components. Bioaerosols are present in both indoor and outdoor environments. For the indoor environment, locations that provide appropriate temperature and moisture conditions and a food source for biological growth may become problematic.

In microbiology, **reservoirs** allow microorganisms to survive, **amplifiers** allow them to proliferate, and **disseminators** effectively distribute bioaerosols. Building components and systems may have only one factor, or all three; for instance, a cooling tower is an ideal location for growth and dispersal of microbial contaminants and can be the reservoir, amplifier, and disseminator for *Legionella* (harboring microorganisms in scale, allowing them to proliferate, and generating an aerosol).

Both the physical and biological properties of bioaerosols need to be understood. For a microorganism to cause illness in building occupants, it must be transported in sufficient dose to a susceptible

Licensed for single user. © 2021 ASHRAE, Inc.

occupant. Airborne infectious particles behave physically in the same way as any other aerosol-containing particles with similar size, density, and electrostatic charge. The major difference is that bioaerosols may cause disease by several mechanisms (infection, allergic disease, immunomodulation, irritation, toxicosis), depending on the organism, dose, and susceptibility of the exposed population. Although microorganisms exist normally in indoor environments, the presence of abundant moisture and nutrients in interior spaces results in the growth of fungi, bacteria, protozoa, algae, or even nematodes (Arnow et al. 1978; Morey and Jenkins 1989; Morey et al. 1986; Strindehag et al. 1988). Thus, humidifiers, water spray systems, and wet porous surfaces can be reservoirs and sites for growth. Excessive air moisture (Burge 1995) and floods (Hodgson et al. 1985) can also result in proliferation of these microorganisms indoors. Turbulence associated with the start-up of air-handling unit plenums may also elevate concentrations of bacteria and fungi in occupied spaces (Buttner and Stetzenbach 1999; Yoshizawa et al. 1987).

Building Surface and Material Sources. Floors and floor coverings can be reservoirs for organisms that are subsequently resuspended into the air. Routine activity, including walking and vacuuming (Buttner et al. 2002), may even promote resuspension (Cox 1987). Some viruses may persist up to eight weeks on nonporous surfaces (Mbithi et al. 1991).

Building Water System Sources. Although potable water is usually delivered to buildings free of biological hazards, once the water enters the facility it becomes the responsibility of facility managers and owners to ensure that its microbial and chemical quality does not degrade. In fact, biological hazards associated with processes in building water systems cause considerable disease. Most cases of legionellosis, for example, result from exposure to potable water in buildings (McCoy 2005; WHO 2007).

Nonpotable water is a well-known source of infective agents and of noninfective biological particles. Baylor et al. (1977) demonstrated the sequestering of small particles by foam and their subsequent dispersal through bubble bursting. This dispersal may take place in surf, river sprays, or artificial sources such as whirlpools.

Building Occupant Sources. People are an important source of bacteria and viruses in indoor air. Infected humans can release virulent agents from skin lesions or disperse them by coughing, sneezing, or talking. Other means for direct release include sprays of saliva and respiratory secretions during dental and respiratory therapy procedures. Large droplets can transmit infectious particles to those close to the disseminator, and smaller particles can remain airborne for short or very long distances (Moser et al. 1979). Droplet nuclei can be transported over long distances, resulting in infection transmission, as shown by studies of SARS in Hong Kong (Li et al. 2005a, 2005b). Studies of student dorms found lower ventilation associated with higher incidence of infectious diseases (Sun et al. 2011).

Health Effects. The presence of microorganisms in indoor environments may cause infective and/or allergic building-related illnesses (Burge 1989; Morey and Feeley 1988). Some microorganisms under certain conditions may produce microbial volatile organic chemicals (MVOCs) (Hyppel 1984; Mason et al. 2010) that are malodorous. Microorganisms must remain viable to cause infection, although nonviable particles may promote an allergic disease, which is an immunological response. An organism that does not remain virulent in the airborne state cannot cause infection, regardless of how many units of organisms are deposited in the human respiratory tract. Virulence depends on factors such as relative humidity, temperature, oxygen, pollutants, ozone, and ultraviolet light (Burge 1995), each of which can affect survival and virulence differently for different microorganisms. Harmful chemicals and fragments produced by microorganisms can also cause irritant responses and carry biologically active metabolites (e.g., allergens, ligands) that trigger inflammatory immune responses (Drummond and Brown 2011; Green et al. 2005).

A wide variety of bacteria, fungi, and protozoa are prevalent in building water systems and can cause disease by transmission through water and air. Clinically important microorganisms known to cause disease in health care facilities include the bacteria *Legionella*, *Pseudomonas*, and *Mycobacterium*; the fungi *Aspergillus* and *Fusarium*; and the protozoa *Cryptosporidium*, *Giardia*, and *Acanthamoeba*.

Fungal Pathogens. Many fungal genera are widely distributed in nature and are common in the soil and on decaying vegetation, dust, and other organic debris (Levetin 1995). Fungi that have a filamentous structure are called **molds**, and reproduce by spores. Mold spores are small (2 to 10 μm in diameter), readily dispersed by water splash and air currents, and may remain airborne for long periods of time (Lighthart and Stetzenbach 1994; Streifel et al. 1989).

Dampness and mold growth/colonization in buildings have long been thought to cause increased health problems for occupants (Institute of Medicine 2004). In recent decades, multiple high-profile incidents have generated great public concern about mold in buildings, but also conflicting opinions on which health effects can be caused by dampness and mold, and on how to determine the level of risk in a building. Published reviews and meta-analyses of the scientific literature have clarified the available scientific basis for defining these health risks (Bornehag et al. 2001; Fisk et al. 2007, 2010; Institute of Medicine 2004; Kreiger et al. 2010; Mendell et al. 2011; WHO 2009).

Health studies have led to a consensus among health scientists that the presence in buildings of (1) visible water damage, (2) damp materials, (3) visible mold growth/colonization, or (4) mold odor indicates an increased risk of respiratory disease for occupants. In addition, evidence is accumulating that the more extensive, widespread, or severe these indicators, the greater the health risks. Known health risks include development of asthma, allergies, and respiratory infections; triggering of asthma attacks; and increased wheeze, cough, difficulty breathing, and other symptoms. Associations with other kinds of health effects have not been substantiated, but also have not been ruled out. Available information also suggests that children are more sensitive to dampness and mold than adults. The specific dampness-related agents that cause these respiratory health effects, whether molds, bacteria, other microbial agents, or dampness-related chemical emissions, have not been identified.

There also is consensus that the traditional methods used to measure molds in air or dust do not reliably predict increased health risks. Some newer methods of measuring mold, although promising, have not been proven to be better predictors of health effects than simply assessing the presence of evident dampness or mold growth/colonization. Therefore, current practices for the collection, analysis, and interpretation of environmental samples for mold-derived aerosols cannot be used to quantify health risks posed by dampness and mold growth/colonization in buildings or to guide health-based actions. Also, current consensus does not justify the differentiation of some molds as toxic or especially hazardous to healthy individuals. The only types of evidence that have been related consistently to adverse health effects are the presence of current or past water damage, damp materials, visible mold, and mold odor, *not* the number or type of mold spores or the presence of other markers of mold growth/colonization in indoor air or dust.

Bacterial Pathogens. Diseases produced by the bacterial genus ***Legionella*** are collectively called legionelloses. More than 45 species have been identified, with over 20 isolated from both environmental and clinical sources. Conditions favorable for *Legionella* spp. growth include water temperatures of 25 to 42°C; stagnant conditions; presence of scale, sediment, and biofilms; and the presence of amoebas (Geary 2000). Diseases produced by *Legionella pneumophila* include Legionnaires' disease (pneumonia form) and Pon-

Licensed for single user. © 2021 ASHRAE, Inc.

tiac fever (flulike form). *L. pneumophila* serogroup 1 is the most frequently isolated from nature and most frequently associated with disease. Infection rates are affected by the strain of *L. pneumophila* as well as host condition (e.g., tobacco smoking, excessive weight, age). Legionellosis is not rare, but it is rarely diagnosed, and is severely underreported, often lost among other causes of pneumonia. McCoy (2006) estimated that, every day in the United States, an average of about 11 people die from legionellosis, and another 57 are infected but survive, often with lifelong debilitation.

In a review of waterborne infections from building water systems, it was estimated that 1400 deaths occur each year in the United States from *Pseudomonas aeruginosa*, another waterborne bacteria commonly found in building water systems (Anaissie et al. 2002).

Viral Pathogens. Outbreaks of infection in indoor air may also be caused by **viruses**. Viruses are readily disseminated from infected individuals, but cannot reproduce outside a host cell. Therefore, they do not reproduce in building structures or air-handling components, but can be distributed throughout buildings through duct systems and on air currents. Human-to-human dispersal is common. In one example, most of the passengers in an airline cabin developed influenza following exposure to one acutely ill person (Moser et al. 1979). In this case, the plane had been parked on a runway for several hours with the ventilation system turned off. Severe acute respiratory syndrome (SARS), caused by a corona virus similar to the common cold, was assumed to result from large droplet transmission; however, in an outbreak in a high-rise apartment, airborne transmission was the primary mode of disease spread, likely through dissemination from a bathroom drain (Yu et al. 2004). Ventilation and airflows in buildings were shown to affect the transmission of SARS in this outbreak and another outbreak in a hospital ward (Li et al. 2005a, 2005b).

Infectious diseases are transmitted through three primary routes: (1) direct contact and fomites (i.e., inanimate objects that transport infectious organisms from one individual to another), (2) large droplets [generally with a mass median aerodynamic diameter (MMAD) > 10 μm], and (3) fine particles, sometimes called *droplet nuclei* (MMAD < 10 μm) (Mandell et al. 1999). Routes of disease transmission that are not related to the environment or to buildings (e.g., blood-borne, insect vectored) exist, but are beyond the scope of this chapter. Table 4 lists infections considered transmissible by air.

Nonviable Biological Substances. **Allergic reactions** are an immunological response to foreign glycol proteins. The causes of the rapid increase in allergies all over the world are not known, but indoor exposures to new chemicals (e.g., plasticisers, flame retardants, biocides, cleaning products) and alterations to the gut microflora driving immunomodulation are suspected, as well as reduced ventilation. When a person has acquired an allergy, an acute attack may develop after dermal contact or inhalation of particles containing allergens (e.g., enzymes, mite and cockroach excreta, pet dander, pollen). The severity of immunological reactions to bioaerosols can vary dramatically, from discomfort (allergic rhinitis and sinusitis) to life-threatening asthma. Allergy testing in conjunction with a carefully obtained history may be helpful in identifying an offending agent. In cases of more severe illness, it may be necessary to remove an affected individual from exposure, even after appropriate abatement and exposure control methods have been instituted in the building, though this is the purview of the clinicians, and not of building professionals.

Exposure Guidelines for Bioaerosols. At present, numerical guidelines for bioaerosol exposure in indoor environments and for infectious pathogens that can spread via airborne routes are not available for the following reasons (Morey 1990):

- Incomplete data on background concentrations and types of microorganisms indoors, especially as affected by geographical, seasonal, and building parameters
- Incomplete understanding of and ability to measure routes of exposure, internal dose, and intermediate and ultimate clinical effects
- Absence of epidemiological data relating bioaerosol exposure indoors to illness
- Enormous variability in types of microbial particles, including viable cells, dead spores, toxins, antigens, MVOCs, and viruses
- Large variation in human susceptibility to microbial particles, making estimates of health risk difficult

Exposure Control Strategies. Because of the wide variety of pathogens and sources, a range of bioaerosol exposure control strategies may be required. Typically, these strategies should focus on source control (including good housekeeping and proper HVAC system operation and maintenance), but dilution ventilation, local exhaust ventilation, disinfection procedures, space pressure control, and filtration may also be considered.

Moisture control is the key to mold growth/colonization control. Molds need both food and water to survive; because molds can digest most things, water is the key factor that limits mold growth. The presence of **water damage**, **dampness**, **visible mold**, or **mold odor** in schools, workplaces, residences, and other indoor environments is unhealthy. It is not recommended to measure indoor microorganisms or the presence of specific microorganisms to attempt to determine the level of health hazard or the need for urgent remediation. Instead, address water damage, dampness, visible mold, and mold odor by (1) identifying and correcting the **source of water** that may allow microbial growth or contribute to other problems, (2) rapidly drying or removing **damp materials**, and (3) cleaning or removing **mold colonies and mold-colonized (moldy) materials**, as rapidly and safely as possible, to protect the health and well being of building occupants, especially children. More detailed information may be found in Harriman et al. (2001) and ASHRAE's (2003) *Mold and Moisture Management in Buildings*.

ASHRAE *Standard* 188 and *Guideline* 12 provides environmental and operational guidance for safe operation of building water systems to minimize the risk of Legionnaires' disease.

2.2 GASEOUS CONTAMINANTS

Gaseous contaminants include both true gases (which have boiling points less than room temperature) and vapors of liquids with boiling points above normal indoor temperatures. It also includes both volatile organic compounds and inorganic air contaminants.

Volatile organic compounds (VOCs) include 4- to 16-carbon alkanes, chlorinated hydrocarbons, alcohols, aldehydes, ketones, esters, terpenes, ethers, aromatic hydrocarbons (such as benzene and toluene), and heterocyclic hydrocarbons. Also included are chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs), which are still used as refrigerants in existing installations, although production and importation have been phased out for environmental protection (Calm and Domanski 2004). More information on classifications, characteristics, and measurement methods can be found in Chapter 11.

Inorganic gaseous air contaminants include ammonia, nitrogen oxides, ozone, sulfur dioxide, carbon monoxide, and carbon dioxide. Although the last two contain carbon, they are by tradition regarded as inorganic chemicals.

The most common units of measurement for gaseous contaminants are parts per million by volume (ppm) and milligrams per cubic metre (mg/m^3). For smaller quantities, parts per billion (ppb) and micrograms per cubic metre ($\mu g/m^3$) are used. The relationship between these units of measure is also described in Chapter 11.

Industrial Environments

Exposures and Sources. In the industrial environment, a wide variety of gaseous contaminants may be emitted as process

Table 4 Pathogens with Potential for Airborne Transmission

Pathogen	Aerosol Route of Transmission
Anthrax	Inhalation of spores
Arenaviruses	Inhalation of small particle aerosols from rodent excreta
Aspergillosis	Inhalation of airborne conidia (spores)
Blastomycosis	Conidia, inhaled in spore-laden dust
Brucellosis	Inhalation of airborne bacteria
Chickenpox/shingles (*Varicella zoster* virus)	Droplet or airborne spread of vesicle fluid or respiratory tract secretions
Coccidioidomycosis	Inhalation of infective arthroconidia
Adenovirus	Transmitted through respiratory droplets
Enteroviruses (Coxsackie virus)	Aerosol droplet spread
Cryptococcosis	Presumably by inhalation
Human parvovirus	Contact with infected respiratory secretions
Rotavirus	Possible respiratory spread
Norwalk virus	Airborne transmission from fomites
Hantavirus	Presumed aerosol transmission from rodent excreta
Histoplasmosis	Inhalation of airborne conidia
Influenza	Airborne spread predominates
Lassa virus	Aerosol contact with excreta of infected rodents
Legionellosis	Epidemiological evidence supports airborne transmission
Lymphocytic choriomeningitis	Oral or respiratory contact with virus contaminated excreta, food, or dust
Measles	Airborne by droplet spread
Melioidosis	Inhalation of soil dust
Meningitis (*Neisseria meningitidis*)	Respiratory droplets from nose and throat
(*Haemophilus influenzae*)	Droplet infection and discharges from nose and throat
(*Streptococcus pneumoniae*)	Droplet spread and contact with respiratory secretions
Mumps	Airborne transmission or droplet spread
Nocardia	Acquired through inhalation
Paracoccidioidomycosis	Presumably through inhalation of contaminated soil or dust
Whooping cough (*Bordetella pertussis*)	Direct contact with discharges from respiratory mucous membranes of infected persons by the airborne route
Plague (*Yersinia pestis*)	Rarely airborne droplets from human patients. In the case of deliberate use, plague bacilli would possibly be transmitted as an aerosol.
Pneumonia (*Streptococcus pneumoniae*)	Droplet spread
(Mycoplasma pneumoniae)	Probably droplet inhalation
(*Chlamydia pneumoniae*)	Possibilities include airborne spread
Psittacosis (*Chlamydia psittaci*)	Inhalation of agent from desiccated droppings, secretions, and dust from feathers of infected birds
Q fever (*Coxiella burnetti*)	Commonly through airborne dissemination of *Coxiellae* in dust
Rabies	Airborne spread has been demonstrated in a cave where bats were roosting, and in laboratory settings, but this occurs very rarely.
Rhinitis/common cold (rhinovirus, coronavirus, parainfluenza, respiratory syncytial virus)	Presumably inhalation of airborne droplets
Rubella	Droplet spread
Smallpox (*Variola major*)	Via respiratory tract (droplet spread)
Sporotrichosis	Pulmonary sporotrichosis presumably arises through inhalation of conidia
Staphylococcal diseases	Airborne spread rare, but has been demonstrated in patients with associated viral respiratory disease
Streptococcal diseases	Large respiratory droplets. Individuals with acute upper respiratory tract (especially nasal) infections are particularly likely to transmit infection.
Toxoplasmosis	Inhalation of sporulated oocysts was associated with one outbreak
Tuberculosis	Exposure to tubercle bacilli in airborne droplet nuclei
Tularaemia (*Francisella tularensis*)	By inhalation of dust from contaminated soil, grain, or hay

Source: Tang et al. (2006).
Note: Virtually all these pathogens are also transmissible by direct contact. Pathogens in **bold** are those considered to have potential for long-distance airborne transmission.

Licensed for single user. © 2021 ASHRAE, Inc.

by-products (e.g., paints, solvents, and welding fumes) or as accidental spills and releases.

Health Effects of Industrial Exposures. Given that tens of thousands of contaminants are regularly used by industry, possible health effects can range from mild skin or eye irritation and headaches, to failure of major organs or systems and death.

Exposure standards and specific health effects for various industrial contaminants are discussed in the following section.

Exposure Standards. Occupational exposure standards or legal concentration limits are established by a country or by a widely recognized organization like the WHO, with specific clarifications or recommendations for each state, province, or territory. In the United States, the Occupational Safety and Health Administration (OSHA) sets permissible exposure limits (PELs) for toxic and hazardous substances, which are enforceable workplace regulatory standards. These are published yearly in the *Code of Federal Regulations* (29CFR1910, Subpart Z) and intermittently in the *Federal Register*. Most of the regulatory levels were derived from those recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) and Agency for Toxic Substances and Disease Registry (ATSDR). The health effects on which these standards were based can be found in their publications. ACGIH reviews data on a regular basis and publishes annual revisions to their Threshold Limit Values (TLVs®).

The National Institute for Occupational Safety and Health (NIOSH), a research agency of the U.S. Department of Health and Human Service, conducts research and makes recommendations to prevent work-related illness and injury. NIOSH publishes the *Registry of Toxic Effects and Chemical Substances* (RTECS), as well as numerous criteria on recommended standards for occupational exposures. Some compounds not listed by OSHA are covered by NIOSH, and their recommended exposure limits (RELs) are sometimes lower than the legal requirements set by OSHA. The NIOSH *Pocket Guide to Chemical Hazards* (NIOSH 2007) condenses these references and is a convenient reference for engineering purposes.

The harmful effects of gaseous pollutants depend on both short-term peak concentrations and the time-integrated exposures received by the person. OSHA defined three periods for concentration averaging and assigned allowable levels that may exist in these categories in workplaces for over 490 compounds, mostly gaseous contaminants. Abbreviations for concentrations for the three averaging periods are

AMP = acceptable maximum peak (for a short exposure)
ACC = acceptable ceiling concentration (not to be exceeded during an 8 h shift, except for periods where an AMP applies)
TWA8 = time-weighted average (not to be exceeded in any 8 h shift of a 40 h week)

The respective levels are presented in Tables Z-1, Z-2, and Z-3 of 29CFR1910.1000, *Occupational safety and health standards: Air contaminants*.

In non-OSHA literature, the AMP is sometimes called a short-term exposure limit (STEL), and a TWA8 is sometimes called a threshold limit value (TLV). NIOSH (1997) also lists values for the toxic limit that is immediately dangerous to life and health (IDLH).

Standards differ for industrial and nonindustrial environments (EHD 1987). A Canadian National Task Force developed guideline criteria for residential indoor environments (Health Canada 2010), and the World Health Organization (WHO) published indoor air quality guidelines for Europe (WHO 2010). Table 5 compares some of these guidelines with occupational criteria for selected contaminants.

Exposure Control Strategies. Gaseous contaminant control strategies include eliminating or reducing sources, local exhaust, general dilution ventilation, and using personal protective devices such as respirators. The most effective control strategy is source control. If source control is not possible, local exhaust ventilation can often be the most cost-effective method of controlling airborne contaminants. General dilution ventilation is often the least effective means of control. Ventilation and local exhaust for industrial environments are discussed more thoroughly in Chapters 31 and 32 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Nonindustrial Environments

Gaseous contaminants of concern in nonindustrial environments include organic compounds, refrigerants, and inorganic gases.

Volatile Organic Compounds.

Sources. Indoor sources of VOCs include building materials, furnishings, cleaning products, office and HVAC equipment, ETS [including products from e-cigarettes (vaping)], marijuana smoke, and people and their personal care products. Outdoor sources of VOCs may also enter the building through various airflow paths, including intake air and infiltration through the building envelope.

Health Effects. Potential adverse health effects of VOCs in nonindustrial indoor environments are not well understood, but may include (1) irritant effects, including perception of unpleasant odors, mucous membrane irritation, and exacerbation of asthma; (2) systemic effects, such as fatigue and difficulty concentrating; and (3) toxic, chronic effects, such as carcinogenicity (Girman 1989).

Chronic adverse health effects from VOC exposure are of concern because some VOCs commonly found in indoor air are human (benzene) or animal (chloroform, trichloroethylene, carbon tetrachloride, p-dichlorobenzene) carcinogens. Some other VOCs are also genotoxic. Theoretical risk assessment studies suggest that risk from chronic VOC exposures in residential indoor air is greater than that associated with exposure to VOCs in the outdoor air or in drinking water (McCann et al. 1987; Tancrede et al. 1987).

A biological model for acute human response to low levels of VOCs indoors is based on three mechanisms: sensory perception of the environment, weak inflammatory reactions, and environmental stress reaction (Mølhave 1991). A growing body of literature summarizes measurement techniques for the effects of VOCs on nasal (Koren 1990; Koren et al. 1992; Meggs 1994; Mølhave et al. 1993; Ohm et al. 1992) and ocular (Franck et al. 1993; Kjaergaard 1992; Kjaergaard et al. 1991) mucosa. It is not well known how different sensory receptions to VOCs are combined into perceived comfort and the sensation of air quality. This perception is apparently related to stimulation of the olfactory sense in the nasal cavity, the gustatory sense on the tongue, and the common chemical sense (Cain 1989; Mølhave 1991).

Cometto-Muñiz and Cain (1994a, 1994b) addressed the independent contribution of the trigeminal and olfactory nerves to the detection of airborne chemicals. Smell is experienced through olfactory nerve receptors in the nose. Nasal pungency, described as common chemical sensations such as prickling, irritation, tingling, freshness, stinging, and burning, is experienced through nonspecialized receptors of the trigeminal nerve in the face. Odor and pungency thresholds follow different patterns related to chemical concentration. Odor is often detected at much lower levels. A linear correlation between pungency thresholds of homologous series (of alcohols, acetates, ketones, and alkylbenzenes, all relatively nonreactive agents) suggests that nasal pungency relies on a physicochemical interaction with a susceptible biophase within the cell membrane. Through this nonspecific mechanism, low, subthreshold levels of a wide variety of VOCs, as found in many polluted indoor environments, may be additive in sensory impact to produce noticeable sensory irritation.

Exposure Standards. Few standards exist for exposure to VOCs in nonindustrial indoor environments. NIOSH, OSHA, and ACGIH have regulatory standards or recommended limits for industrial occupational exposures [ACGIH (annual); NIOSH 1992]. With few

exceptions, concentrations observed in nonindustrial indoor environments fall well below (100 to 1000 times lower) published pollutant-specific occupational exposure limits. The California Office of Environmental Health Hazard Assessment (OEHHA 2016a) established chronic reference exposure limits (cRELs) for inhalation exposure to 80 compounds, including many VOCs found in indoor air, which can be used as guidelines for establishing appropriate IAQ criteria regarding specific VOCs of interest.

Total VOC (TVOC) concentrations were suggested as an indicator of the ability of combined VOC exposures to produce adverse health effects. This approach is no longer supported, because the irritant potential and toxicity of individual VOCs vary widely, and measured concentrations are highly dependent on the sampling and analytical methods used (Hodgson 1995). In controlled exposure experiments, odors become significant at roughly 3 mg/m^3. At 5 mg/m^3, objective effects were seen, in addition to subjective reports of irritation. Exposures for 50 min to 8 mg/m^3 of synthetic mixtures of 22 VOCs led to significant irritation of mucous membranes in the eyes, nose, and throat (Kjærgaard et al. 1991).

Exposure Control Strategies. VOC control strategies include source elimination or reduction, local exhaust, air cleaning, and general dilution ventilation. Several emission testing standards [e.g., BIFMA *Standard* M7.1; CDPH (2010)] have been established to promote the use and production of low-VOC-emission materials and products. Air-cleaning technologies include physical and chemical adsorption, photocatalytic oxidization, and dynamic botanical filtration (Wang 2011). Caution is needed to ensure that target pollutants are sufficiently removed and no by-products with adverse health effects are produced (Pei and Zhang 2011; Zhang et al. 2011). Ventilation requirements and other means of control of gaseous contaminants are discussed more thoroughly in Chapter 16 of this volume and Chapter 47 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Semivolatile organic compounds (SVOCs) include phthalates, alkylphenols, flame retardants, polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and pesticides. Many SVOCs are associated with adverse health outcomes in laboratory animal studies and in some environmental epidemiology studies.

Sources. Indoor sources of SVOCs include consumer products and building materials such as detergents, toys, lotions, nail polish, perfume, cosmetics, shampoo, electronic equipment (e.g., computers, televisions), pesticides, furniture foam or stuffing, shower curtains, vinyl flooring, and PVC products. In general, since

the 1950s, levels of volatile organic compounds (VOCs) increased and then decreased. During this same period, levels of SVOCs, such as those used as plasticizers and flame retardants, have increased and remain high (Rudel and Perovich 2009; Weschler 2009). Table 6 lists compounds representative of SVOCs encountered indoors (Weschler and Nazaroff 2008).

Table 6 Selected SVOCs Found in Indoor Environments

Chemical Class	SVOC	CAS Number	Formula
Biocides and preservatives			
Antimicrobials	Triclosan	3380-34-5	$C_{12}H_7Cl_3O_2$
Antioxidants	Butylated hydroxytoluene (BHT)	128-37-0	$C_{15}H_{24}O$
Fungicides	Tributyltin oxide (TBTO)	56-35-9	$C_{24}H_{54}OSn_2$
Wood preservatives	Pentachlorophenol (PCP)	87-86-5	C_6HCl_5O
Combustion by-products			
Environmental tobacco smoke	Nicotine	54-11-5	$C_{10}H_{14}N_2$
Polychlorinated dibenzo-p-dioxins	2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD)	1746-01-6	$C_{12}H_4Cl_4O_2$
Polycyclic aromatic hydrocarbons	Benzo[a]pyrene (BaP)	50-32-8	$C_{20}H_{12}$
	Phenanthrene	85-01-8	$C_{14}H_{10}$
	Pyrene	129-00-0	$C_{16}H_{10}$
Degradation products/residual monomers			
Phenols	Bisphenol A	80-05-7	$C_{15}H_{16}O_2$
Flame retardants			
Brominated flame retardants	2,2′,4,4′,5,5′-Hexabromodiphenyl ether (BDE-153)	68631-49-2	$C_{12}H_4Br_6O$
	2,2′,4,4′,5-Pentabromodiphenyl ether (BDE-99)	60348-60-9	$C_{12}H_5Br_5O$
	2,2′,4,4′-Tetrabromodiphenyl ether (BDE-47)	5436-43-1	$C_{12}H_6Br_4O$
Chlorinated flame retardants	Perchloropentacyclodecane (mirex)	2385-85-5	$C_{10}Cl_{12}$
Phosphate esters	Tris(chloropropyl) phosphate	13674-84-5	$C_9H_{18}Cl_3O_4P$
Heat transfer fluids			
Polychlorinated biphenyls (PCBs)	2,2′,5,5′-tetrachloro-1,1′-biphenyl (PCB 52)	35693-99-3	$C_{12}H_6Cl_4$
	2,2′,4,4′,5,5′-hexachloro-1,1′-biphenyl (PCB 153)	35065-27-1	$C_{12}H_4Cl_6$
Microbial emissions			
Sesquiterpenes	Geosmin	23333-91-7	$C_{12}H_{22}O$
Personal care products			
Musk compounds	Galaxolide	1222-05-5	$C_{18}H_{26}O$
Petrolatum constituents	n-Pentacosane	629-99-2	$C_{25}H_{52}$
Pesticides/termiticides/herbicides			
Carbamates	Propoxur	114-26-1	$C_{11}H_{15}NO_3$
Organochlorine pesticides	Chlordane	57-74-9	$C_{10}H_6Cl_8$
	p,p′-DDT	50-29-3	$C_{14}H_9Cl_5$
Organophosphate pesticides	Chlorpyrifos	2921-88-2	$C_9H_{11}Cl_3NO_3PS$
	Diazinon	333-41-5	$C_{12}H_{21}N_2O_3PS$
	Methyl parathion	298-00-0	$C_8H_{10}NO_5PS$
Pyrethroids	Cyfluthrin	68359-37-5	$C_{22}H_{18}Cl_2FNO_3$
	Cypermethrin	52315-07-8	$C_{22}H_{19}Cl_2NO_3$
	Permethrin	52645-53-1	$C_{21}H_{20}Cl_2O_3$
Synergists	Piperonyl butoxide	51-03-6	$C_{19}H_{30}O_5$
Plasticizers			
Adipate esters	Di(2-ethylhexyl) adipate (DEHA)	103-23-1	$C_{22}H_{42}O_4$
Phosphate esters	Triphenylphosphate (TPP)	115-86-6	$C_{18}H_{15}O_4P$
Phthalate esters	Butylbenzyl phthalate (BBzP)	85-68-7	$C_{19}H_{20}O_4$
	Dibutyl phthalate (DBP)	84-74-2	$C_{16}H_{22}O_4$
	Di(2-ethylhexyl) phthalate (DEHP)	117-81-7	$C_{24}H_{38}O_4$
Sealants			
Silicones	Tetradecamethylcycloheptasiloxane (D7)	107-50-6	$C_{14}H_{42}O_7Si_7$
Stain repellents, oil and water repellents			
Perfluorinated surfactants	N-ethyl perfluorooctane sulfonamidoethanol (EtFOSE)	1691-99-2	$C_{12}H_{10}F_{17}NO_3S$
	N-methylperfluorooctane sulfonamidoethanol (MeFOSE)	24448-09-7	$C_{11}H_8F_{17}NO_3S$
Surfactants (nonionic), emulsifiers, coalescing agents			
Alkylphenol ethoxylates	4-Nonylphenol	104-40-5	$C_{15}H_{24}O$
Coalescing agents	3-Hydroxy-2,2,4-Trimethylpentyl-1-Isobutyrate (Texanol)	25625-77-4	$C_{12}H_{24}O_3$
Terpene oxidation products			
	Pinonaldehyde	2704-78-1	$C_{10}H_{16}O_2$
Water disinfection products			
	3-Chloro-4-(dichloromethyl)-5-hydroxy-2(5H)-furanone (MX)	77439-76-0	$C_5H_3Cl_3O_3$
Waxes, polishes, and essential oils			
Fatty acids	Stearic acid (octadecanoic acid)	57-11-4	$C_{18}H_{36}O_2$
	Linoleic acid	60-33-3	$C_{18}H_{32}O_2$
Sesquiterpenes	Caryophyllene	87-44-5	$C_{15}H_{24}$

Health Effects. Exposures to SVOCs in nonindustrial indoor environments have been associated with adverse health effects in a number of recent studies. Exposures to these compounds have been linked to endocrine disruptions in both animals and in humans, poor semen quality (motility, number), birth abnormalities in anogenital distance, and premature sexual development (genital and reproductive anomalies such as hypospadias) (Hauser and Calafat 2005; Rogan and Ragan 2007; Swan 2008). Human exposure to SVOCs has also been studied by monitoring concentrations of metabolites in body fluids such as in urine or blood. Results show that people are exposed to multiple SVOCs everywhere, and that children often are more exposed than adults (EPA 2011). Biomonitoring data suggest that over 95% of the U.S. population is exposed to phthalates (Kato et al. 2004), and the body burden for polybrominated diphenyl ethers (PBDEs, used in flame retardants) in North Americans is 10 to 100 times higher than in Europeans because of the much higher indoor exposure of the U.S. population (Harrad et al. 2006; Sjodin et al. 2008).

When determining SVOC exposure pathways, remember that SVOCs can be either gaseous or condensed. They are redistributed from their original source to indoor air and subsequently to all interior surfaces, including airborne particles, settled dust, fixed surfaces, and human surfaces (Rudel and Perovich 2009; Weschler and Nazaroff 2008; Xu et al. 2010). Indeed, contaminated indoor environments have recently been recognized as a significant uptake pathway for SVOCs (Harrad et al. 2006; Xu et al. 2010). Exposure routes of SVOCs include diet, inhalation, dermal absorption, and oral ingestion of dust (Hauser and Calafat 2005; Weschler and Nazaroff 2008, 2012). Diet, the only pathway that is relatively insensitive to the indoor presence of SVOCs, is considered the dominant source for total intake (body burden) for many SVOCs. However, awareness is growing of potential exposure through inhalation, inadvertent ingestion, or skin adsorption (Hauser and Calafat 2005; Weschler and Nazaroff 2012). For some SVOCs, indoor exposures via these three pathways appear to be larger than that resulting from diet. Table 7 provides the indoor concentrations and body burden of selected semivolatile organic compounds.

Table 7 Indoor Concentrations and Body Burden of Selected Semivolatile Organic Compounds

Chemical	Typical Reported Concentrations in Indoor Environments		U.S. Body Burdens, 95th Percentile: in Blood, ng/g Serum; in Urine, μg/g Creatinine
	Air, ng/m³	Dust, μg/g	
Biocides and preservatives			
Triclosan	—	0.2 to 2	360 (urine)
Tributyltin oxide (TBTO)	—	0.01 to 0.1	—
Pentachlorophenol (PCP)	0.4 to 4	0.2 to 2	2.3 (urine)
Combustion by-products			
Nicotine	200 to 2000	10 to 100	2.2 (blood)
Benzo[a]pyrene (BaP)	0.02 to 0.2	0.2 to 2	0.18 (urine)
Phenanthrene	10 to 100	0.2 to 2	1.7 (urine)
Pyrene	1 to 10	0.2 to 2	0.24 (urine)
Degradation products/residual monomers			
Bisphenol A	0.5 to 5	0.2 to 2	11 (urine)
Flame retardants			
2,2′,4,4′,5,5′-Hexabromodiphenyl ether (BDE-153, hexa BDE)	0.002 to 0.02	0.03 to 0.3	0.44 (blood)
2,2′,4,4′,5-Pentabromodiphenyl ether (BDE-99, penta BDE)	0.03 to 0.3	0.4 to 4	0.28 (blood)
2,2′,4,4′-Tetrabromodiphenyl ether (BDE-47, tetra BDE)	0.06 to 0.6	0.3 to 3	1.1 (blood)
Perchloropentacyclodecane (Mirex)	—	—	0.41 (blood)
Tris(chloropropyl) phosphate	6 to 60	0.3 to 3	—
Heat transfer fluids			
2,2′,5,5′-tetrachloro-1,1′-biphenyl (PCB 52)	0.2 to 2.0	0.05 to 0.5	0.089 (blood)
2,2′,4,4′,5,5′-hexachloro-1,1′-biphenyl (PCB 153)	0.1 to 1.0	0.007 to 0.07	0.85 (blood)
Personal care products			
Galaxolide	25 to 250	0.5 to 5	—
Pesticides/termiticides/herbicides			
Propoxur	0.8 to 8	0.05 to 0.5	<1 (urine)
Chlordane	0.5 to 5	0.04 to 0.4	0.35 (blood)
p,p′-DDT	0.2 to 2	0.1 to 1	0.18 (blood)
Chlorpyrifos	1 to 10	0.08 to 0.8	9.2 (urine)
Diazinon	1 to 5	0.02 to 0.2	<1 (urine)
Methyl parathion	0.05 to 0.5	0.01 to 0.1	2.9 (urine)
Cyfluthrin	0.1 to 1.0	0.08 to 0.8	Common metabolite: 2.6 (urine)
Cypermethrin	—	0.08 to 0.8	
Permethrin	0.1 to 0.7	0.2 to 2	3.8 (urine)
Piperonyl butoxide	0.1 to 1.0	0.1 to 1.0	—
Plasticizers			
Di(2-ethylhexyl) adipate (DEHA)	5 to 15	2 to 10	—
Triphenylphosphate (TPP)	0.1 to 1	2 to 20	—
Butylbenzyl phthalate (BBzP)	5 to 80	15 to 150	90 (urine)
Dibutyl phthalate (DBP)	200 to 1200	20 to 200	81 (urine)
Di(2-ethylhexyl) phthalate (DEHP)	50 to 500	300 to 900	270 (urine)
Stain repellents, oil/water repellents			
N-ethyl perfluorooctane sulfonamidoethanol (EtFOSE)	0.5 to 3	30 to 500	Common metabolite (PFOS): 55 (blood)
N-methylperfluorooctane sulfonamidoethanol (MeFOSE)	0.5 to 5	30 to 300	
Surfactants (nonionic), emulsifiers, coalescing agents			
4-Nonlyphenol	40 to 400	0.8 to 8	1.4 (urine)
Texanol 2	500 to 5000	—	—

Exposure Standards. Few standards exist for exposure to SVOCs in nonindustrial indoor environments. NIOSH, OSHA, EPA, and ACGIH have regulatory standards or recommended limits for industrial occupational exposures for inhalation, some of which are given in Table 5. The California Environmental Protection Agency's Office of Environmental Health Hazard Assessment (OEHHA 2016b) maintains a list of VOCs and other chemicals known to the state to cause cancer or reproductive toxicity.

Lately, a new generation of scientific tools has emerged to rapidly measure responses from cells, tissues, and organisms following exposure to chemicals, including SVOCs. The goal of such methods is to rapidly screen and prioritize chemicals for more detailed toxicity testing (Judson et al. 2010). However, activities to compile exposure data to develop novel approaches and metrics to screen and evaluate chemicals based on biologically relevant human exposures are still in their initial stages.

Exposure Control Strategies. SVOC control strategies include source identification, elimination or reduction. Weschler and Nazaroff (2008) argued, based on theoretical considerations, that ventilation is not as effective in reducing indoor concentrations of SVOCs as it is in reducing indoor concentrations of VOCs. Although recent modeling studies indicate that ventilation has a limited ability to reduce indoor levels of most airborne SVOCs and thus the ability to reduce human exposures (Liang and Xu 2011; Xu et al. 2010), Weschler and Nazaroff (2008) showed that ventilation is generally ineffective in controlling human exposure because of the long-term persistence of condensed SVOCs. Laboratory studies have demonstrated the small impact that ventilation has on indoor airborne levels of di(2-ethylhexyl) phthalate (DEHP), a compound used as a plasticizer (Xu et al. 2010). Field studies are needed to evaluate the impact of ventilation on different types of SVOCs under realistic indoor conditions. Furthermore, there is also a lack of literature documenting SVOC exposure reductions via air cleaning. Table 7 shows indoor concentrations and body burdens of selected SVOCs.

Inorganic Gases.

Sources. Inorganic gases in the nonindustrial environment may come from a combination of outdoor air and indoor sources, including occupants (e.g., respiration, toiletries), processes (e.g., combustion, office equipment), and indoor air chemistry (e.g., reaction between ozone and alkenes).

Health Effects. **Carbon monoxide** is a chemical asphyxiant. Inhalation of CO causes a throbbing headache because hemoglobin has a greater affinity for CO than for oxygen (about 240 times greater), and because of a detrimental shift in the oxygen dissociation curve. Carbon monoxide inhibits oxygen transport in the blood by forming carboxyhemoglobin and inhibiting cytochrome oxidase at the cellular level. Cobb and Etzel (1991) suggested that CO poisoning at home represented a major preventable disease. Moolenaar et al. (1995) had similar findings, and suggested that motor vehicles and home furnaces were primary causes of mortality. Girman et al. (1998) identified both fatal outcomes and "episodes" and classed them by cause:

Cause	Fatal Outcomes, %	Nonfatal Episodes, %
Motor vehicles	35.9	30.6
Appliance combustion	34.8	39.9
Small appliances	4.5	5.2
Camping equipment	2.2	2.3
Fires	5.6	5.0
Grills/hibachis	13.4	13.3
Unknown	3.6	3.7

In a review of CO exposures in the United States from 2001 to 2003, the Centers for Disease Control (CDC 2005) found that nearly 500 people died and over 15 000 were treated in emergency departments each year after unintentional, non-fire-related CO exposures. Of cases with known sources, the most common source of CO was furnaces (18.5%), followed by motor vehicles (9.1%). Inappropriate use of portable generators, a growing problem, resulted in around 50 deaths per year from 2002 to 2005 (CPSC 2006).

Carbon dioxide can become dangerous not as a toxic agent but as a simple asphyxiant. When concentrations exceed 35 000 ppm, central breathing receptors are triggered and cause the sensation of shortness of breath. At progressively higher concentrations, central nervous system dysfunction begins because of displacement of oxygen. Measured concentrations of CO_2 in nonindustrial environments are typically below 1000 ppm, but can occasionally be as high as 2500 ppm, depending on occupant density and outdoor air ventilation rates (Persily 2015a). Nevertheless, much confusion exists regarding the significance of indoor CO_2 and its effects on occupant health and comfort (ASHRAE 2009).

Inhalation of **nitric oxide (NO)** causes methemoglobin formation, which adversely affects the body by interfering with oxygen transport at the cellular level. NO exposures of 3 ppm have been compared to carbon monoxide exposures of 10 to 15 ppm (Case et al. 1979, in EPA 1991).

Nitrogen dioxide (NO_2) is a corrosive gas with a pungent odor, with a reported odor threshold between 0.11 and 0.22 ppm. NO_2 has low water solubility, and is therefore inhaled into the deep lung, where it causes a delayed inflammatory response. Increased airway resistance has been reported at 1.5 to 2 ppm (Bascom 1996). NO_2 is reported to be a potential carcinogen through free radical production (Burgess and Crutchfield 1995). At high concentrations, NO_2 causes lung damage directly by its oxidant properties, and may cause health effects indirectly by increasing host susceptibility to respiratory infections. Health effects from exposures to ambient outdoor concentrations or in residential situations are inconsistent, especially in studies relating to exposures from gas cooking stoves (Samet et al. 1987). Indoor concentrations of NO_2 often exceed ambient concentrations because of the presence of strong indoor sources and a trend toward more energy-efficient (tighter) homes. Acute toxicity is seldom seen from NO_2 produced by unvented indoor combustion, because insufficient quantities of NO_2 are produced. Chronic pulmonary effects from exposure to combinations of low-level combustion pollutants are possible, however (Bascom et al. 1996).

Sulfur dioxide (SO_2) is a colorless gas with a pungent odor detected at about 0.5 ppm (EPA 1991). Because SO_2 is quite soluble in water, it readily reacts with moisture in the respiratory tract to irritate the upper respiratory mucosa. Concomitant exposure to fine particles, an individual's depth and rate of breathing, and preexisting disease can influence the degree of response to SO_2 exposure.

Ozone (O_3) is a pulmonary irritant and has been known to alter human pulmonary function at concentrations of approximately 0.12 ppm (Bates 1989). However, inhaling ozone at considerably lower concentrations (e.g., about 0.080 ppm) has been shown to decrease respiratory function in healthy children (Spektor et al. 1988a). Outdoor ozone levels as low as 0.020 ppm have been shown to increase mortality, and levels below 0.010 ppm may be required for safety (ASHRAE 2011). These levels are far below current federal NAAQS levels of 0.075 ppm. Reducing ozone levels indoors to as low as reasonably achievable (ALARA) levels by various means is recommended.

Products of ozone reactions are often more irritating than precursors. Ozone and isoprene react to form free radicals, formaldehyde, methacrolein, and methyl vinyl ketone. Ozone and terpenoids react to form free radicals, secondary ozonides, formaldehyde, acrolein, hydrogen peroxide, organic peroxides, dicarbonyls, carboxylic acids, and submicron particles.

Ozone reacts with many organic chemicals and airborne particulate matter commonly found indoors. Weschler (2006) summarizes current knowledge of these reactions and their products, which

Licensed for single user. © 2021 ASHRAE, Inc.

include both stable reaction products that may be more irritating than their chemical precursors (Mølhave et al. 2005; Tamas et al. 2006; Weschler and Shields 2000) and relatively short-lived products that are highly irritating and may also have chronic toxicity or carcinogenicity (Destaillats et al. 2006; Nazaroff et al. 2006; Weschler 2000; Wilkins et al. 2001; Wolkoff et al. 2000).

Chen et al. (2012) assessed the influence of indoor exposure to outdoor ozone on short-term mortality in U.S. communities. When air with ozone passes through loaded filters, the downstream concentrations of submicron-sized particles is higher than the upstream concentration. Ozone removal efficiencies on used filters change by one of at least two different removal mechanisms: reactions with compounds on the filter media after manufacturing, and reactions with compounds on captured particles (Beko et al. 2007).

The scientific literature is well developed in showing the effect of ozone on respiratory function and health effects of exposure to elevated levels of ozone (Lippmann 1993; Spektor et al. 1988b, 1991; Thurston et al. 1997). A critical review of the health effects of ozone is provided by Lippmann (1989).

Exposure to ozone at 0.060 to 0.080 ppm causes inflammation, bronchoconstriction, and increased airway responsiveness. The EPA's BASE study of over 100 randomly selected typical U.S. office buildings (Apte et al. 2007) found a clear statistical relationship between ambient ozone concentrations and building-related health symptoms, despite the fact that only one building had a workday average ambient ozone concentration greater than the then-current 8 h national ambient air quality standards [NAAQS; see EPA (2016a)] level of 0.080 ppm.

Ambient air ozone concentrations down to 0.020 ppm are associated with increased mortality (Bell et al. 2005). Several researchers have explored the relationship between ozone and mortality (Bates 2005; Goodman 2005; Ito et al. 2005; Levy et al. 2005).

Although ozone uptake (deposition velocity v_d) on diverse materials varies greatly (e.g., from 0.025 m/h for aluminum to 28 m/h for gypsum board), uptakes in a wide variety of building types and occupancies are within a fairly narrow range (between 0.9 and 1.5 m/h).

Inhalation exposures to gaseous oxides of nitrogen (NO_x), sulfur (SO_2), and ozone (O_3) occur in residential and commercial buildings. These air pollutants are of considerable concern because of the potential for acute and chronic respiratory tract health effects in exposed individuals, particularly individuals with preexisting pulmonary disease.

Exposure Standards and Guidelines. Currently, there are no specific U.S. government standards for nonindustrial occupational exposures to air contaminants. Occupational exposure criteria are health based; that is, they consider only healthy workers, and not necessarily individuals who may be unusually responsive to the effects of chemical exposures. The U.S. EPA's (2016a) NAAQS are also health-based standards designed to protect the general public from the effects of hazardous airborne pollutants (see Chapter 11). Table 8 is not meant as a health-based guideline for evaluating indoor exposures to inorganic gases; rather, it is intended for comparison and consideration by investigators of the indoor environment. These criteria may not be completely protective for all occupants.

Exposure Control Strategies. Inorganic gas contaminant control strategies include source elimination or reduction, local exhaust, space pressure control, general dilution ventilation, and gaseous air cleaning. Ventilation requirements and other means of control of gaseous contaminants are discussed more thoroughly in Chapter 16 of this volume and Chapter 47 of the 2019 *ASHRAE Handbook—HVAC Applications*.

The by-products of indoor air chemistry can be limited by using carbon-based filters in locations where outdoor ozone concentrations commonly approach or exceed the NAAQS.

Table 8 Inorganic Gas Comparative Criteria

Contaminant	ACGIH TWA[a]	U.S. EPA NAAQS[b]
Nitric oxide	25 ppm	0.100 ppm (1 h)[c]
Nitrogen dioxide	0.2 ppm	0.100 ppm (1 h)[c] 0.053 ppm[d]
Sulfur dioxide	0.25 ppm[e]	0.075 ppm (200 µg/m³)[f] 0.5 ppm (1333 µg/m³)[g]
Ozone	0.05 to 0.2 ppm	0.070 ppm (8 h in specified form)[h]

[a]TWA: 8 h time-weighted average (unless otherwise noted)
[b]National Ambient Air Quality Standards
[c]Three-year average of the 98th percentile of the daily maximum 1 h average
[d]Annual mean
[e]Ceiling value, not to be exceeded during any part of working exposure
[f]Three-year average of the 99th percentile of the daily maximum 1 h average
[g]Not to be exceeded more than once per year
[h]Annual fourth-highest daily maximum 8 h concentration, averaged over three years.

3. PHYSICAL AGENTS

Physical factors in the indoor environment include thermal conditions (temperature, moisture, air velocity, and radiant energy); mechanical energy (noise and vibration); and electromagnetic radiation, including ionizing (radon) and nonionizing [light, radiofrequency, and extremely low frequency (ELF)] magnetic and electric fields. Physical agents can act directly on building occupants, interact with indoor air quality factors, or affect human responses to the indoor environment. Though not categorized as indoor air quality factors, physical agents often affect perceptions of indoor air quality.

3.1 THERMAL ENVIRONMENT

The thermal environment affects human health in that it affects body temperature regulation and heat exchange with the environment. A normal, healthy, resting adult's internal or core body temperatures are very stable, with variations seldom exceeding 0.5 K. The internal temperature of a resting adult, measured orally, averages about 37.0°C; measured rectally, it is about 0.5 K higher. Core temperature is carefully modulated by an elaborate physiological control system. In contrast, skin temperature is basically unregulated and can (depending on environmental temperature) vary from about 31 to 36°C in normal environments and activities. It also varies between different parts of the skin, with the greatest range of variation in the hands and feet.

Range of Healthy Living Conditions

Environmental conditions for good thermal comfort minimize effort of the physiological control system. The control system regulates internal body temperature by varying the amount of blood flowing to different skin areas, thus increasing or decreasing heat loss to the environment. Additional physiological response includes secreting sweat, which can evaporate from the skin in warm or hot environments, or increasing the body's rate of metabolic heat production by shivering in the cold. For a resting person wearing trousers and a long-sleeved shirt, thermal comfort in a steady state is experienced in a still-air environment at 24°C. A zone of comfort extends about 1.5 K above and below this optimum level (Fanger 1970).

An individual can minimize the need for physiological (involuntary) responses to the thermal environment, which generally are perceived as uncomfortable, in various ways. In a cool or cold environment, these responses include increased clothing, increased activity, or seeking or creating an environment that is warmer. In a warm or hot environment, the amount of clothing or level of physical activity can be reduced, or an environment that is more

Licensed for single user. © 2021 ASHRAE, Inc.

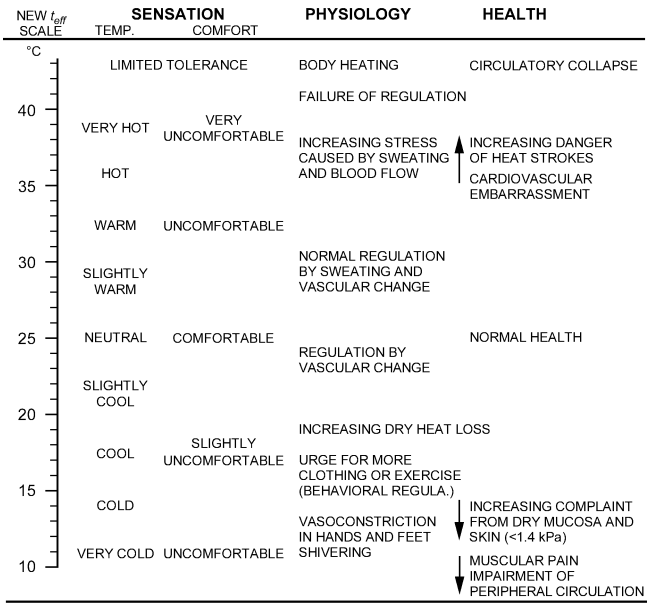

Fig. 1 Related Human Sensory, Physiological, and Health Responses for Prolonged Exposure

conducive to increased heat loss can be created. Some human responses to the thermal environment are shown in Figure 1.

Cardiovascular and other diseases and aging can reduce the capacity or ability of physiological processes to maintain internal body temperature through balancing heat gains and losses. Thus, some people are less able to deal with thermal challenges and deviations from comfortable conditions. Metabolic heat production tends to decrease with age, as a result of decreasing basal metabolism together with decreased physical activity. Metabolic heat production at age 80 is about 20% less than that at age 20, for comparable size and mass. People in their eighties, therefore, may prefer an environmental temperature about 1.5 K warmer than people in their twenties. Older people may have reduced capacity to secrete sweat and to increase their skin blood flow, and are therefore more likely to experience greater strain in warm and hot conditions, as well as in cool and cold conditions. However, the effect of age on metabolism and other factors related to thermal response varies considerably from person to person, and care should be taken in applying these generalizations to specific individuals.

Hypothermia

Hypothermia is defined as a core body temperature of less than 35°C. Hypothermia can result from environmental cold exposure, but may also be induced by other conditions, such as metabolic disorders and drug use. Occupational hypothermia occurs in workers in a cold environment when heat balance cannot be met while maintaining work performance. Elderly persons sitting inactive in a cool room may become hypothermic, because they often fail to observe a slow fall in body temperature (Nordic Conference on Cold 1991).

Deleterious effects of cold on work performance derive from peripheral vasoconstriction and cooling, which slows down the rate of nerve conduction and muscle contraction, and increases stiffness in tendons and connective tissues. This induces clumsiness and increases risk for injury (e.g., in occupational settings). Direct effects of cold include injuries from frostbite (skin freezes at 0 to 2°C) and a condition called **immersion foot**, in which the feet are exposed to wetness and temperatures of 1 to 10°C for more than 12 h, and vasoconstriction and low oxygen supply lead to edema and tissue damage.

Hyperthermia

In hyperthermia, body temperatures are above normal. A deep-body temperature increase of 2 K above normal does not generally impair body function. For example, it is not unusual for runners to have rectal temperatures of 40°C after a long race. An elevated body temperature increases metabolism. However, when body temperature increases above normal for reasons other than exercise, heat illness may develop. Heat illness represents a number of disorders from mild to fatal, which do not depend only on the hyperthermia in itself. In heat stroke, the most severe condition, the heat balance regulation system collapses, resulting in a rapid rise in body temperature. Central nervous system function deteriorates at deep body temperatures above 41 to 42°C. Convulsions may occur above such temperatures, and cells may be damaged. This condition is particularly dangerous for the brain, because lost neurons are not replaced. Thermoregulatory functions of sweating and peripheral vasodilation cease at about 43°C, after which body temperatures tend to rise rapidly if external cooling is not imposed (Blatteis 1998; Hales et al. 1996).

Seasonal Patterns

Ordinary seasonal changes in temperate climates are temporally associated with illness. Many acute and several chronic diseases vary in frequency or severity with time of year, and some are present only in certain seasons. Most countries report increased mortality from cardiovascular disease during colder winter months. Minor respiratory infections, such as colds and sore throats, occur mainly in fall and winter. More serious infections, such as pneumonia, have a somewhat shorter season in winter. Intestinal infections, such as dysentery and typhoid fever, are more prevalent in summer. Diseases transmitted by insects, such as encephalitis and endemic typhus, are limited to summer, because insects are active in warm temperatures only.

Hryhorczuk et al. (1992), Martinez et al. (1989), and others describe a correlation between weather and seasonal illnesses, but correlations do not necessarily establish a causal relationship. Daily or weekly mortality and heat stress in heat waves have a strong physiological basis directly linked to outdoor temperature. In indoor environments, which have well-controlled temperature and humidity, such temperature extremes and the possible adverse effects on health are strongly attenuated.

Climate Change

Impacts to human health can include the direct effects of climate change such as increased ambient temperatures, air pollution, and extreme weather. Additionally, indirect impacts of climate change may include vector-borne diseases and expanded habitats, industrial transitions, emerging industries (e.g., renewable energy, carbon sequestration, "green industries," toxic waste from PV cell fabrication, noise and flickering from wind turbines), increased use of pesticides, and changes in the built environment (Institute of Medicine 2014; NIOSH 2014).

In general, climate change can affect people from these perspectives:

- Amplification of known safety and health hazards such as severe weather events, heat, wildland fire, and infectious disease
- New, unanticipated, or unrecognized hazards (increased infectious disease vector ranges, increase in pesticide use)
- Hazards that result from responses to climate change such as the development of renewable energy, recycling, carbon sequestration, and material substitution (Kiefer and Watson 2015)

Increased Deaths in Heat Waves

The role of weather-induced ambient temperature extremes in producing discomfort, incapacity, and death has been studied extensively (Katayama and Momiyana-Sakamoto 1970). Military

Licensed for single user. © 2021 ASHRAE, Inc.

personnel, deep-mine workers, and other workers occupationally exposed to extremes of high and low temperature have been studied, but the importance of thermal stress affecting both the sick and healthy general population is not sufficiently appreciated. Collins and Lehmann (1953) studied weekly deaths over many years in large U.S. cities and demonstrated the effect of heat waves in producing conspicuous periods of excess mortality. Excess mortality caused by heat waves was of the same amplitude as that from influenza epidemics, but tended to last one week instead of the four to six weeks of influenza epidemics.

Ellis (1972) reviewed heat wave-related excess mortality in the United States. Mortality increases of 30% over background are common, especially in heat waves early in the summer. Much of the increase occurs in the population over age 65, more of it in women than in men, and many deaths are from cardiovascular, cerebrovascular, or respiratory causes (often exacerbated preexisting conditions). Oeschli and Buechley (1970) studied heat-related deaths in Los Angeles heat waves of 1939, 1955, and 1963. Kilbourne et al. (1982) suggested that the same risk factors (i.e., age, low income, and African-American derivation) persist in more recent heat death epidemics.

Among the most notable lethal heat waves in Europe are Athens in 1987 and 1988 (Giles et al. 1990), Seville in 1988 (Diaz et al. 2002), Valencia in 1991 and 1993 (Ballester et al. 1997), London in 1995 (Hajat et al. 2002), the Netherlands between 1979 and 1991 (Kunst et al. 1993), and Paris in 2003 (Thirion et al. 2005). In the 2003 Parisian heat wave, about 3000 people died.

The temperature/mortality relation varies greatly by latitude and climatic zone (McMichael et al. 2006). Occupants of hotter cities are more affected by colder temperatures, and occupants of colder cities are more affected by warmer temperatures. People living in urban environments are at greater risk than those in nonurban regions. Thermally inefficient housing and the so-called urban heat island effect amplify and extend the rise in temperatures (especially overnight).

Hardy (1971) showed the relationship of health data to comfort on a psychrometric diagram (Figure 2). The diagram contains ASHRAE effective temperature (ET*) lines and lines of constant skin moisture level or skin wettedness. Skin wettedness is defined as that fraction of the skin covered with water to account for the observed evaporation rate. The ET* lines are loci of constant physiological strain, and also correspond to constant levels of physiological discomfort (i.e., slightly uncomfortable, comfortable, and very comfortable) (Gonzalez et al. 1978). Skin wettedness, as an indicator of strain (Berglund and Cunningham 1986; Berglund and Gonzalez 1977) and the fraction of the skin wet with perspiration, is fairly constant along an ET* line. Numerically, ET* is the equivalent temperature at 50% rh that produces the strain and discomfort of the actual condition. The summer comfort range is between an ET* of 23 and 26°C. In this region, skin wettedness is less than 0.2. Heat strokes occur generally when ET* exceeds 34°C (Bridger and Helfand 1968). Thus, the ET* line of 35°C is generally considered dangerous. At this point, skin wettedness will be 0.4 or higher.

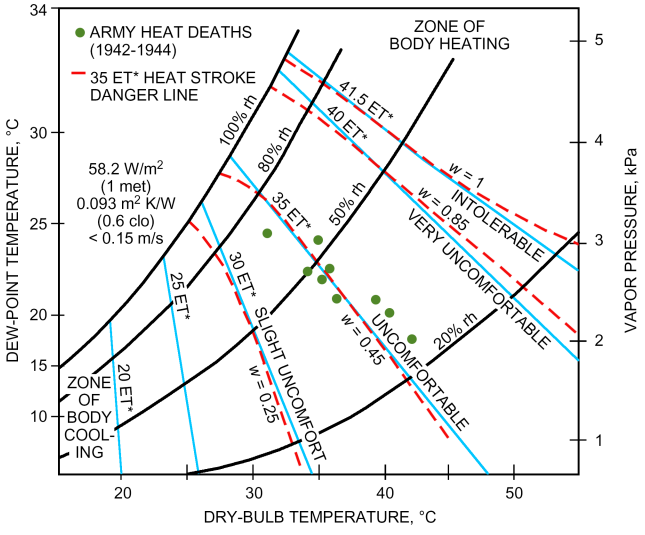

Fig. 2 Isotherms for Comfort, Discomfort, Physiological Strain, Effective Temperature (ET*), and Heat Stroke Danger Threshold

The dots in Figure 2 correspond to heat stroke deaths of healthy male U.S. soldiers assigned to sedentary duties in midwestern army camp offices (Shickele 1947). Older people can be expected to respond less well to thermal challenges than do healthy soldiers. This was apparently the case in the Illinois heat wave study (Bridger and Helfand 1968), where the first wave with a 33% increase in death rate and an ET* of 29.5°C affected mainly the over-65-year-old group. The studies suggest that the "danger line" represents a threshold of significant risk for young healthy people, and that the danger tends to move to lower values of ET* with increasing age.

Effects of Thermal Environment on Specific Diseases

Cardiovascular diseases are largely responsible for excess mortality during heat waves. For example, Burch and DePasquale (1962) found that heart disease patients with decompensation (i.e., inadequate circulation) were extremely sensitive to high temperatures, and particularly to moist heat. However, both cold and hot temperature extremes have been associated with increased coronary heart disease deaths and anginal symptoms (Teng and Heyer 1955).

Both acute and chronic respiratory diseases often increase in frequency and severity during extreme cold weather. No increase in these diseases has been noted in extreme heat. Additional studies of hospital admissions for acute respiratory illness show a negative correlation with temperature after removal of seasonal trends (Holland 1961). Symptoms of chronic respiratory disease (bronchitis, emphysema) increase in cold weather, probably because reflex constriction of the bronchi adds to the obstruction already present. Greenberg (1964) found evidence of cold sensitivity in asthmatics: emergency room treatments for asthma increased abruptly in local hospitals with early and severe autumn cold spells. Later cold waves with even lower temperatures produced no such effects, and years without early extreme cold had no asthma epidemics of this type. Patients with cystic fibrosis are extremely sensitive to heat because their reduced sweat gland function greatly diminishes their ability to cope with increased temperature (Kessler and Anderson 1951).

Itching and chapping of the skin are influenced by (1) atmospheric factors, particularly cold and dry air; (2) frequent washing or wetting of skin; and (3) low indoor humidities. Although skin itching is usually a winter cold-climate illness in the general population, it can be caused by excessive summer air conditioning (Gaul and Underwood 1952; Susskind and Ishihara 1965).

People suffering from chronic illness (e.g., heart disease) or serious acute illnesses that require hospitalization often manage to avoid serious thermal stress. Katayama and Momiyana-Sakamoto (1970) found that countries with the most carefully regulated indoor climates (e.g., Scandinavian countries, the United States) have only small seasonal fluctuations in mortality, whereas countries with less space heating and cooling exhibit greater seasonal swings in mortality. For example, mandatory air conditioning in retirement and assisted living homes in the southwest United States has virtually eliminated previously observed mortality increases during heat waves.

Table 9 Approximate Surface Temperature Limits to Avoid Pain and Injury

Material	Contact Time				
	1 s	10 s	1 min	10 min	8 h
Metal, water	65°C	56°C	51°C	48°C	43°C
Glass, concrete	80°C	66°C	54°C	48°C	43°C
Wood	120°C	88°C	60°C	48°C	43°C

Source: ISO *Standard* 13732-1:2006.

Injury from Hot and Cold Surfaces

The skin has cold, warm, and pain sensors to feed back thermal information about surface contacts. When the skin temperature rises above 45°C or falls below about 15°C, sensations from the skin's warm and cold receptors are replaced by those from pain receptors to warn of imminent thermal injury to tissue. The rate of change of skin temperature and not just the actual skin temperature may also be important in pain perception. Skin temperature and its rate of change depend on the temperature of the contact surface, its conductivity, and contact time. Table 9 gives approximate temperature limits to avoid pain and injury when contacting three classes of conductors for various contact times (ISO *Standard* 13732-1).

3.2 ELECTRICAL HAZARDS

Electrical current can cause burns, neural disturbances, and cardiac fibrillation (Billings 1975). The threshold of perception is about 5 mA for direct current, with a feeling of warmth at the contact site. The threshold is 1 mA for alternating current, which causes a tingling sensation.

Resistance of the current pathway through the body is a combination of core and skin resistance. The core is basically a saline volume conductor with very little resistance; therefore, the skin provides the largest component of the resistance. Skin resistance decreases with moisture. If the skin is moist, voltages as low as 2 V (AC) or 5 V (DC) are sufficient to be detected, and voltages as low as 20 V (AC) or 100 V (DC) can cause a 50% loss in muscular control.

The dangerous aspect of alternating electrical current is its ability to cause cardiac arrest by ventricular fibrillation. If a weak alternating current (100 mA for 2 s) passes through the heart (as it would in going from hand to foot), the current can force the heart muscle to fibrillate and lose the rhythmic contractions of the ventricles necessary to pump blood. Unconsciousness and death soon follow if medical aid cannot rapidly restore normal rhythm.

3.3 MECHANICAL ENERGIES

Vibration

Vibration in a building originates from both outside and inside the building. Outdoor sources include blasting operations, road traffic, overhead aircraft, underground railways, earth movements, and weather conditions. Indoor sources include doors closing, foot traffic, moving machinery, elevators, escalators, HVAC systems, and other building services. Vibration is an omnipresent, integral part of the built environment. The effects of vibration on building occupants depend on whether it is perceived by those persons and on factors related to the building, building location, occupants' activities, and perceived source and magnitude of vibration. Factors influencing the acceptability of building vibration are presented in Figure 3.

The combination of hearing, seeing, or feeling vibration determines human response. Components concerned with hearing and seeing are part of the visual environment of a room and can be assessed as such. The perception of mechanical vibration by feeling is generally through the cutaneous and kinesthetic senses at high frequencies, and through the vestibular and visceral senses at low frequencies. Because of this and the nature of vibration sources and

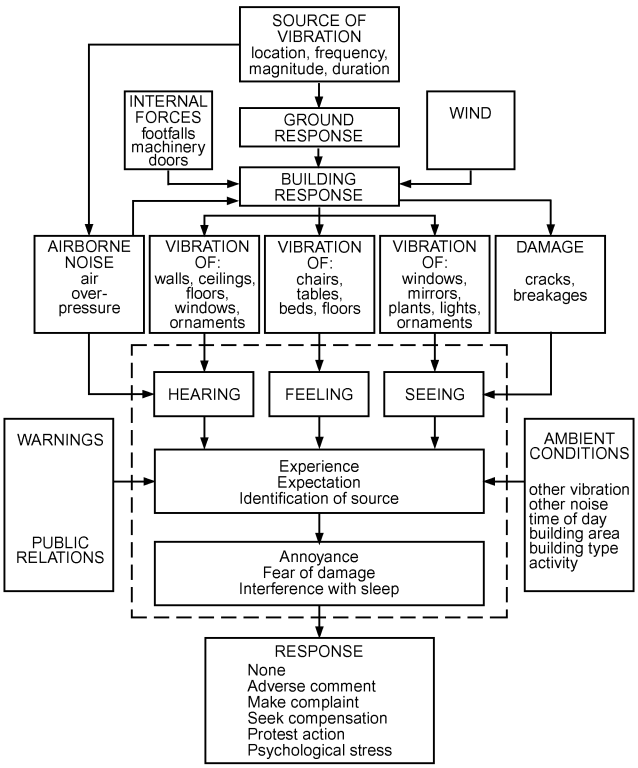

Fig. 3 Factors Affecting Acceptability of Building Vibration

building responses, building vibration may be conveniently considered in two categories: low-frequency vibrations less than 1 Hz and high-frequency vibrations of 1 to 80 Hz.

Measurement and Assessment. Human response to vibration depends on vibration of the body. The main vibrational characteristics are vibration level, frequency, axis (and area of the body), and exposure time. A root-mean-square (RMS) averaging procedure over the time of interest is often used to represent vibration acceleration [m/(s^2·RMS)]. Vibration frequency is measured in cycles per second (Hz), and the vibration axis is usually considered in three orthogonal, human-centered translational directions: up-and-down, side-to-side, and fore-and-aft. Although the coordinate system is centered inside the body, in practice, vibration is measured at the human surface, and measurements are directly compared with relevant limit values or other data concerning human response.

Rotational motions of a building in roll, pitch, and yaw are usually about an axis of rotation some distance from the building occupants. For most purposes, these motions can be considered as the translational motions of the person. For example, a roll motion in a building about an axis of rotation some distance from a seated person has a similar effect as side-to-side translational motions of that person, etc.

Most methods assess building vibrations with RMS averaging and frequency analysis. However, human response is related to the time-varying characteristics of vibration as well. For example, many stimuli are transient, such as those caused by a train passing a building. The vibration event builds to a peak, followed by a decay in level over a total period of about 10 s. The nature of the time-varying event and how often it occurs during a day are important factors that might be overlooked if data are treated as steady-state and continuous.

Standard Limits

Low-Frequency Motion (1 Hz). The most commonly experienced form of slow vibration in buildings is building sway. This

Licensed for single user. © 2021 ASHRAE, Inc.

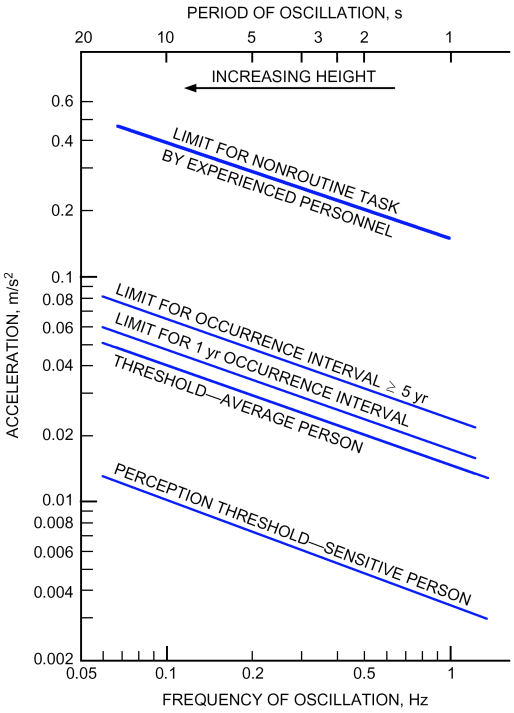

Fig. 4 Acceleration Perception Thresholds and Acceptability Limits for Horizontal Oscillations

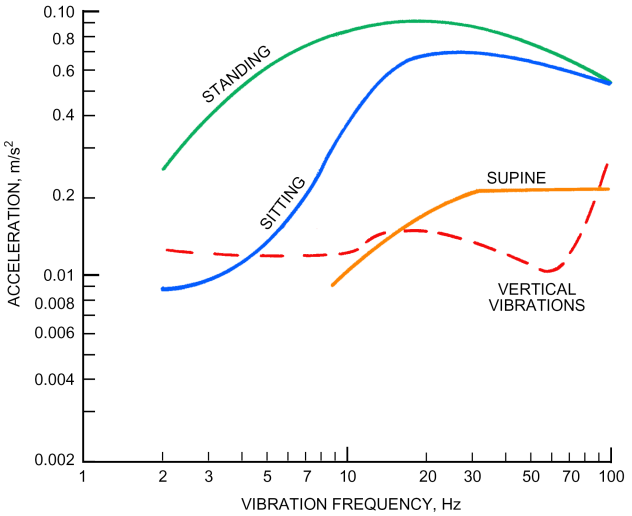

Fig. 5 Median Perception Thresholds to Horizontal (Solid Lines) and Vertical (Dashed Line) Vibrations

motion can be alarming to occupants if there is fear of building damage or injury. Whereas occupants of two-story wood frame houses accept occasional creaks and motion from wind storms or a passing heavy vehicle, such events are not as accepted by occupants of high-rise buildings. Detected motion in tall buildings can cause discomfort and alarm. The perception thresholds of normal, sensitive humans to low-frequency horizontal motion are given in Figure 4 (Chen and Robertson 1972; ISO *Standard* 6897). The frequency range is from 0.06 to 1 Hz or, conversely, for oscillations with periods of 1 to 17 s. The natural frequency of sway of the Empire State Building in New York City, for example, has a period of 8.3 s (Davenport 1988). The thresholds are expressed in terms of relative acceleration, which is the actual acceleration divided by the standard acceleration of gravity g (9.8 m/s^2). The perception threshold to sway in terms of building accelerations decreases with increasing frequency and ranges from 50 to 20 mm/s^2.

For tall buildings, the highest horizontal accelerations generally occur near the top at the building's natural frequency of oscillation. Other parts of the building may have high accelerations at multiples of the natural frequency. Tall buildings always oscillate at their natural frequency, but the deflection is small and the motion undetectable. In general, short buildings have a higher natural frequency of vibration than taller ones. However, strong wind forces energize the oscillation and increase the horizontal deflection, speed, and accelerations of the structure.

ISO *Standard* 6897 states that building motions should not produce alarm and adverse comment from more than 2% of the building's occupants. The level of alarm depends on the interval between events. If noticeable building sway occurs for at least 10 min at intervals of 5 years or more, the acceptable acceleration limit is higher than if this sway occurs annually (Figure 4). For annual intervals, the acceptable limit is only slightly above the normal person's threshold of perception. Motion at the 5-year limit level is estimated to cause 12% to complain if it occurred annually. The recommended limits are for purely horizontal motion; rotational oscillations, wind noise, and/or visual cues of the building's motion exaggerate the sensation of motion, and, for such factors, the acceleration limit is lower.

The upper line in Figure 4 is intended for offshore fixed structures such as oil drilling platforms. The line indicates the level of horizontal acceleration above which routine tasks by experienced personnel would be difficult to accomplish on the structure. Because they are routinely in motion in three dimensions, Figure 4 does not apply to transportation vehicles.

High-Frequency Motion (1 to 80 Hz). Higher-frequency vibrations in buildings are caused by machinery, elevators, foot traffic, fans, pumps, and HVAC equipment. Further, the steel structures of modern buildings are good transmitters of high-frequency vibrations. Sensitivity to these higher-frequency vibrations is indicated in Figure 5 (data from Parsons and Griffin 1988), showing median perception thresholds to vertical and horizontal vibrations in the 2 to 100 Hz frequency range. The average perception threshold for vibrations of this type is from 10 to 90 mm/s^2, depending on frequency and on whether the person is standing, sitting, or lying down.

People detect horizontal vibrations at lower acceleration levels when lying down than when standing. However, a soft bed decouples and isolates a person fairly well from vibrations of the structure. The threshold to vertical vibrations is nearly constant at approximately 12 mm/s^2 for both sitting and standing positions from 2 to 100 Hz. This agrees with observations by Reiher and Meister (1931).

Many building spaces with critical work areas (surgery, precision laboratory work) are considered unacceptable if vibration is perceived by the occupants. In other situations and activities, perceived vibration may be acceptable. Parsons and Griffin (1988) found that accelerations twice the threshold level were unacceptable to occupants in their homes. A method of assessing acceptability in buildings is to compare the vibration with perception threshold values (Table 10).

Sound and Noise

In general terms, sound transmitted through air consists of oscillations in pressure above and below ambient atmospheric pressure. A vibrating object causes high- and low-pressure areas to be formed; these areas propagate away from the source. The entire mechanical energy spectrum includes infrasound and ultrasound as well as audible sound (Figure 6).

Health Effects. Hearing loss is generally considered the most undesirable effect of noise exposure, although there are other effects.

Licensed for single user. © 2021 ASHRAE, Inc.

Table 10 Ratios of Acceptable to Threshold Vibration Levels

Place	Time	Continuous or Intermittent Vibration	Impulse or Transient Vibration Several Times per Day
Critical work areas	Day or night	1	1
Residential	Day/night	2 to 4/1.4	30 to 90/1.4 to 20
Office	Day or night	4	60 to 128
Workshop	Day or night	8	90 to 128

Note: Ratios for continuous or intermittent vibration and repeated impulse shock range from 0.7 to 1.0 for hospital operating theaters (room) and critical working areas. In other situations, impulse shock can generally be much higher than when vibration is more continuous.

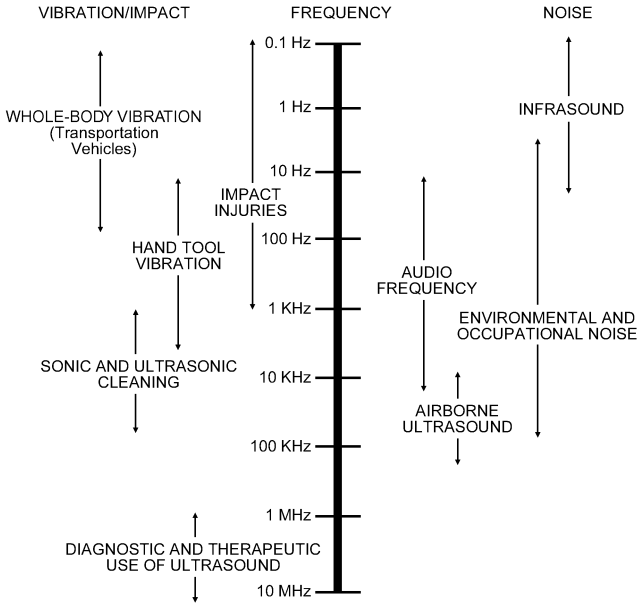

Fig. 6 Mechanical Energy Spectrum

Tinnitus, a ringing in the ears, is really the hearing of sounds that do not exist. It often accompanies hearing loss. **Paracusis** is a disorder where a sound is heard incorrectly; that is, a tone is heard, but has an inappropriate pitch. **Speech misperception** occurs when an individual mistakenly hears one sound for another (e.g., when the sound for *t* is heard as a *p*).

Hearing loss can be categorized as conductive, sensory, or neural. **Conductive** hearing loss results from a general decrease in the amount of sound transmitted to the inner ear. Excessive ear wax, a ruptured eardrum, fluid in the middle ear, or missing elements of bone structures in the middle ear are all associated with conductive hearing loss. These are generally not occupationally related and are generally reversible by medical or surgical means. **Sensory** hearing losses are associated with irreversible damage to the inner ear. Sensory hearing loss is further classified as (1) presbycusis, loss caused as the result of aging; (2) noise-induced hearing loss (industrial hearing loss and sociacusis, which is caused by noise in everyday life); and (3) nosoacusis, losses attributed to all other causes. **Neural** deficits are related to damage to higher centers of the auditory system.

Noise-induced hearing loss is believed to occur in the most sensitive individuals among those exposed for 8 h per day over a working lifetime at levels of 75 dBA, and for most people similarly exposed to 85 dBA.

Even when below levels that can cause adverse health effects, sound and noise can lead to reduced indoor environmental quality and potentially other unhealthy situations. For example, people often react to noisy mechanical equipment by shutting the equipment off

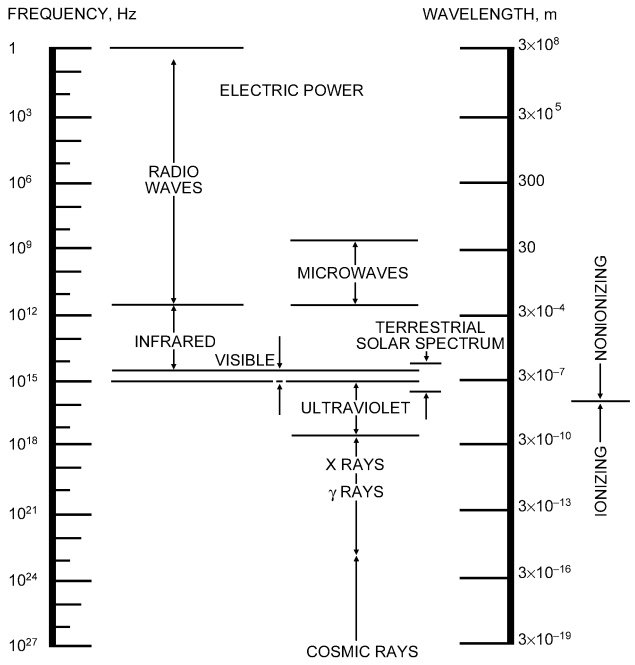

Fig. 7 Electromagnetic Spectrum

or blocking openings that provide a transmission pathway for the noise. Shutting off ventilation systems can lead to unhealthy indoor environments. Blocking some openings, such as those designed to provide combustion air, can also cause problems. Therefore, selecting components that are unlikely to lead to occupant dissatisfaction can be important in providing good indoor environmental quality.

For methods to address potential sound and noise problems, see Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications*.

3.4 ELECTROMAGNETIC RADIATION

Radiation energy is emitted, transmitted, or absorbed in wave or particulate form. This energy consists of electric and magnetic forces, which, when disturbed in some manner, produce electromagnetic radiation. Electromagnetic radiation is grouped into a spectrum arranged by frequency and/or wavelength. The product of frequency and wavelength is the speed of light (3×10^8 m/s). The spectrum includes ionizing, ultraviolet, visible, infrared, microwave, radio, and extremely low frequency (ELF) (Figure 7). Table 11 presents these electromagnetic radiations by their range of energies, frequencies, and wavelengths. The regions are not sharply delineated from each other and often overlap. It is convenient to divide these regions as listed in Table 11, because of the nature of the physical and biological effects.

Ionizing Radiation

Ionizing radiation is the part of the electromagnetic spectrum with very short wavelengths and high frequencies, and it has the ability to ionize matter. These ionizations tend to be very damaging to living matter. Background radiation that occurs naturally in the environment is from cosmic rays and naturally occurring radionuclides. It has not been established whether exposure at the low dose rate of average background levels is harmful to humans.

The basic standards for permissible air concentrations of radioactive materials are those of the National Committee on Radiation Protection, published by the National Bureau of Standards as *Handbook* 69 (NBS 1969). Industries operating under licenses

Table 11 Energy, Wavelength, and Frequency Ranges for Electromagnetic Radiation

Radiation Type	Energy Range	Wavelength Range	Frequency Range
Ionizing	>12.4 eV	<100 nm	>3.00 PHz
Ultraviolet (UV)	12.40 to 3.10 eV	100 to 400 nm	3.00 to 0.75 PHz
Visible	3.10 to 1.63 eV	400 to 760 nm	750 to 395 THz
Infrared (IR)	1.63 to 1.24 meV	760 nm to 1 mm	395 to 0.30 THz
Microwave (MW)	1.24 meV to 1.24 eV	1 mm to 1 m	300 GHz to 300 MHz
Radio-frequency (RF)	1.24 eV to 1.24 peV	1 m to 1 Mm	300 MHz to 300 Hz
Extremely low frequency (ELF)	<1.24 peV	>1 Mm	<300 Hz

from the U.S. Nuclear Regulatory Commission or state licensing agencies must meet requirements of the *Code of Federal Regulations*, Title 10, Part 20. Some states have additional requirements.

An important naturally occurring radionuclide is radon (^{222}Rn), a decay product of uranium in the soil (^{238}U). Radon is chemically inert. Details of units of measurement, typical radon levels, measurement methods and control strategies can be found in Chapter 11.

Health Effects of Radon. Radon is the leading cause of lung cancer among nonsmokers, according to EPA (2016b) estimates. Most information about radon's health risks comes from studies of workers in uranium and other underground mines. The radioactive decay of radon produces a series of radioactive isotopes of polonium, bismuth, and lead. Unlike their chemically inert radon parent, these progeny are chemically active and can attach to airborne particles that subsequently deposit in the lung, or deposit directly in the lung without attachment to particles. Some of these progeny, like radon, are alpha-particle emitters, which can cause cellular changes that may initiate lung cancer when they pass through lung cells (Samet 1989). Thus, adverse health effects associated with radon are caused by exposures to radon decay products, and the amount of risk is assumed to be directly related to the total exposure. Even though it is the radon progeny that present the possibility of adverse health risks, radon itself is usually measured and used as a surrogate for progeny measurements because of the expense involved in accurate measurements of radon progeny.

Exposure Standards. Many countries have established standards for exposure to radon. Some international action levels are listed in Table 12.

About 6% of U.S. homes (i.e., 5.8 million homes) have annual average radon concentrations exceeding 148 Bq/m^3 (4 pCi/L), approaching the action level (150 Bq/m^3) set by the U.S. Environmental Protection Agency (Marcinowski et al. 1994). Because there is no known safe level of exposure to radon, the EPA (2016b) also recommends that all homes be tested for radon, regardless of geographic location, and remedial measures be considered in homes with radon levels between 2 and 4 pCi/L.

Nonionizing Radiation

Ultraviolet radiation, visible light, and infrared radiation are components of sunlight and of all artificial light sources. Microwave and radio-frequency radiation are essential in a wide range of communication technologies and are also in widespread use for heating as in microwave ovens and heat sealers, and for heat treatments of various products. Power frequency fields are an essential and unavoidable consequence of the generation, transmission, distribution, and use of electrical power.

Table 12 2015 Action Levels for Radon Concentration Indoors

Country/Agency	Action Level	
	Bq/m^3	pCi/L
Australia	200	5.4
Austria	200/400	5.4/10.8
Belgium	100/400	2.7/10.8
Canada	200	5.4
Czech Republic	200/400	5.4/10.8
P.R. China	200	5.4
European Union	<300	<8.1
Finland	200/400	5.4/10.8
Germany	100	2.7
International Commission on Radiological Protection (ICRP)	200	5.4
Ireland	200	5.4
Italy	—	10.8
Norway	100 to 200	2.7 to 5.4
Sweden	200	5.4
United Kingdom	100 to 200	2.7 to 5.4
United States	150	4.0
World Health Organization (WHO)	100	2.7

Optical Radiation. Ultraviolet (UV), visible, and infrared (IR) radiation compose the optical radiation region of the electromagnetic spectrum. The wavelengths range from 100 nm in the UV to 1 mm in the IR, with 100 nm generally considered to be the boundary between ionizing and nonionizing. UV wavelengths range from 100 to 400 nm, visible from 400 to 760 nm, and IR from 760 nm to 1 mm.

Optical radiation can interact with a medium by reflection, absorption, or transmission. The skin and eyes are the organs at risk in humans. Optical radiation from any spectral region can cause acute and/or chronic biologic effects given appropriate energy characteristics and exposure. These effects include tanning, burning (erythema), premature "aging," and skin cancer; and dryness, irritation, cataracts, and blindness in the eyes.

The region of the electromagnetic spectrum visible to humans is known as light. There can be biological, behavioral, psychological, and health effects from exposure to light. Assessment of these effects depends on the purpose and application of the illumination. Individual susceptibility varies, with other environmental factors (air quality, noise, chemical exposures, and diet) acting as modifiers. It is difficult, therefore, to generalize potential hazards. **Light pollution** is the presence of unwanted light.

Light penetrating the retina not only allows the exterior world to be seen, but, like food and water, is also used in a variety of metabolic processes. Darkness stimulates the pineal gland to secrete melatonin, which regulates the human biological clock. This, in turn, influences reproductive cycles, sleeping, eating patterns, activity levels, and moods. The color of light affects the way the objects appear. Distortion of color rendition may result in disorientation, headache, dizziness, nausea, and fatigue.

As the daylight shortens, the human body may experience a gradual slowing down, loss of energy, and a need for more sleep. It becomes harder to get to work, and depression or even withdrawal may take place. This type of seasonal depression, brought on by changes in light duration and intensity, is called **seasonal affective disorder (SAD)**. Sufferers also complain of anxiety, irritability, headache, weight gain, and lack of concentration and motivation. This problem is treated through manipulation of environmental lighting (exposure to full-spectrum lighting for extended periods, 12 h/day).

Radio-Frequency Radiation. Just as the body absorbs infrared and light energy, which can affect thermal balance, it can also absorb

Licensed for single user. © 2021 ASHRAE, Inc.

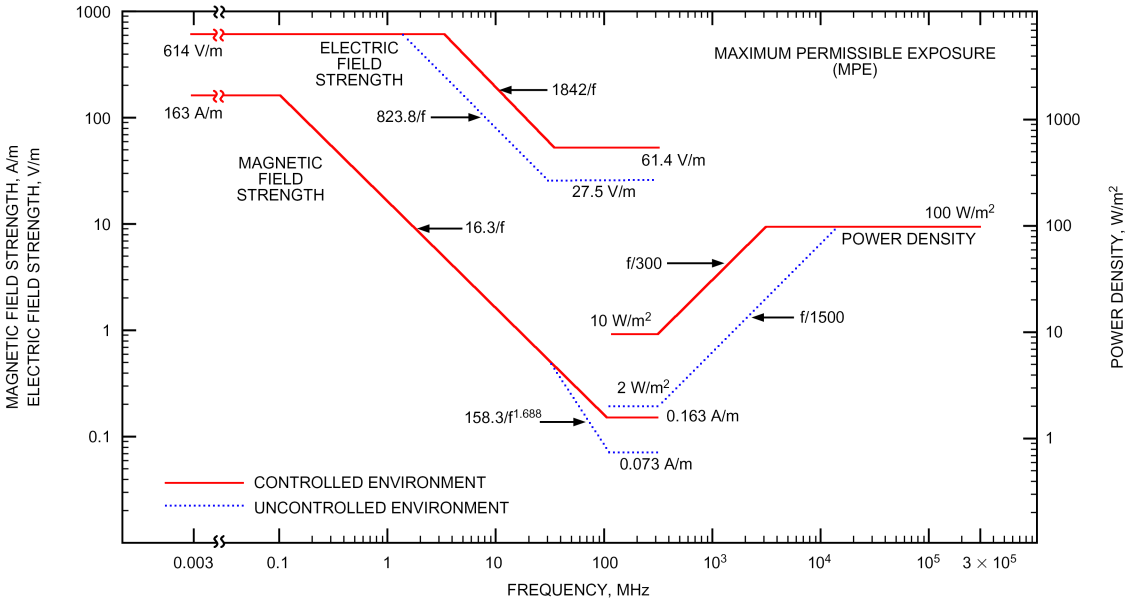

Fig. 8 Maximum Permissible Levels of Radio Frequency Radiation for Human Exposure
(Adapted from ANSI/IEEE *Standard* C95.1-2005)

other longer-wavelength electromagnetic radiation. For comparison, visible light has wavelengths in the range 0.4 to 0.7 μm and infrared from 0.7 to 10 μm, whereas the wavelength of K and X band radar is 12 and 28.6 mm. The wavelength of radiation in a typical microwave oven is 120 mm. Infrared is absorbed within 1 mm of the surface (Murray 1995).

The heat of absorbed radiation raises skin temperature and, if sufficient, is detected by the skin's thermoreceptors, warning the person of possible thermal danger. With increasing wavelength, radiation penetrates deeper into the body. Energy can thus be deposited well beneath the skin's thermoreceptors, making the person less able or slower to detect and be warned of the radiation (Justesen et al. 1982). Physiologically, these longer waves only heat the tissue and, because the heat may be deeper and less detectable, the maximum power density of such waves in occupied areas is regulated (ANSI *Standard* C95.1) (Figure 8). Maximum allowed power densities are less than half of sensory threshold values.

3.5 ERGONOMICS

Ergonomics is the scientific study of the relationship between humans and their work environments to achieve optimum adjustment in terms of efficiency, health, and well-being. Ergonomic designs of tools, chairs, etc., help workers interact more comfortably and efficiently with their environment. In ergonomically designed systems, productivity typically increases and the worker enjoys a healthier working experience. More recently, researchers have distinguished intrinsic ergonomics from extrinsic, or traditional, ergonomics. Intrinsic ergonomics considers how the interface between an individual and the environment affects and relies on specific body parts (e.g., muscles, tendons, bones) and work practices such as force of application, relaxation intervals, styles, and strength reserves that are not adequately considered in simple analyses of the physical environment.

The goals of ergonomic programs range from making work safe and humane, to increasing human efficiency, to creating human well-being. The successful application of ergonomic factors is measured by improved productivity, efficiency, safety, and acceptance of the resultant system design. The design engineer uses not only engineering skills, but also the principles of anatomy, orthopedics, physiology, medicine, psychology, and sociology to apply ergonomics to a design.

Implementing ergonomic principles in the workplace helps minimize on-the-job stress and strain, and prevents cumulative trauma disorders (CTDs). These disorders are subtle injuries that can affect the muscles, tendons, and nerves at body joints, especially the hands, wrists, elbows, shoulders, neck, back, and knees. Carpal tunnel syndrome is an example of a CTD. CTDs most frequently occur as a result of strain from performing the same task on a continuous or repetitive basis. This strain can slowly build over time, until the worker experiences pain and difficulty using the injured part of the body. Higher risks of developing CTDs are encountered when the work task requires repetitive motions, excessive force, or awkward postures. The ergonomics engineer addresses these risk factors by analyzing the task thoroughly and minimizing the repetitive motion, excessive force, and awkward posture.

Poor space ergonomics (Hartkopf and Loftness 1999) and consequent occupant interventions may also directly affect indoor conditions. For example, inappropriate use of cabinets, closets, furniture, partitions, room equipment or other obstructions may block air supply or exhaust vents, reduce airflow rates and temperature or humidity regulation, and disturb airflow (Lee and Awbi 2004). These kinds of problems are often attributed to poor space layout and ventilation design, but usually originate from lack of space availability, such as small room dimensions and high occupant densities. Reduced ventilation rates deteriorate conditions for indoor environmental health, working, and comfort. They may be encountered in overstaffed offices (Mahdavi and Unzeitig 2005) or in demanding environments such as hospital operating theatres (Balaras et al. 2006). The interaction between ergonomics and indoor environmental quality is increasingly important as personalized environmental control systems, such as personal ventilation systems (PVSs), are used to provide customized environment for occupants. This area requires further research.

3.6 OUTDOOR AIR VENTILATION AND HEALTH

Increased outdoor air ventilation reduces indoor concentrations of indoor-generated air pollutants, although the extent of reduction

Licensed for single user. © 2021 ASHRAE, Inc.

varies; in some cases, increased outdoor air ventilation can increase indoor levels of outdoor pollutants. Ventilation rates vary considerably from building to building and over time within individual buildings, depending on occupancy and weather conditions, among other factors (Persily 2015b). Minimum ventilation rates for commercial and residential buildings are specified in ASHRAE *Standards* 62.1 and 62.2, respectively, and for health care facilities in ASHRAE *Standard* 170.

Occupants of office buildings with higher ventilation rates (up to approximately 20 L/s per person) have fewer sick building syndrome (SBS) symptoms at work (Seppänen et al. 1999; Sundell et al. 2011; Wargocki et al. 2002). Statistical analysis of existing data provided a central estimate of the average relationship between SBS symptom prevalence in office workers and ventilation rate (Fisk et al. 2009). This analysis indicates a 23% increase in symptom prevalence as the ventilation rate drops from 10 to 5 L/s per person, and a 29% decrease in symptom prevalence rates as ventilation rate increases from 10 to 25 L/s per person. The uncertainty in these central estimates is considerable, however.

Substantially higher rates of respiratory illness (e.g., 50 to 370%) in high-density buildings (e.g., barracks, jails, nursing homes, health care facilities) and in dorm rooms have been associated with very low ventilation rates (Brundage et al. 1988; Drinka et al. 1996; Hoge et al. 1994; Seppänen et al. 1999; Sun et al. 2011), presumably because lower ventilation rates are likely to result in higher airborne concentrations of infectious viruses and bacteria. Only a few studies have been performed. In a literature review by a multidisciplinary panel (Li et al. 2007), a broader set of evidence was considered to evaluate the role of both ventilation rates and indoor airflow patterns in respiratory disease. The review panel concluded that "there is strong and sufficient evidence" to demonstrate that lower ventilation rates and indoor airflow from infected to uninfected people are associated with increased transmission of infectious diseases "such as measles, tuberculosis, chickenpox, influenza, smallpox, and SARS."

In offices, a 35% decrease in short-term absence was associated with a doubling of ventilation rate from 12 to 24 L/s per person (Milton et al. 2000). In elementary-grade classrooms, on average, for each 100 ppm decrease in the difference between indoor and outdoor CO_2 concentrations, there was a 1 to 2% relative decrease in the absence rate (Shendell et al. 2004). Given the relationship of CO_2 concentrations with ventilation rates, for each 1 L/s per person increase in ventilation rate, the relative decrease in absence rates was estimated to be 1 to 4%. This relationship applied over an estimated ventilation rate range of 2.5 to 15 L/s per person, and should not be applied outside those limits. Data relating building ventilation rates and absence rates are very limited.

In residences, very little research has been conducted on the relationship of ventilation rates with the health of occupants. A Norwegian study (Oie et al. 1999) of young children found that low home ventilation rates were not associated with an increase in bronchial obstruction (i.e., reduced breathing airflows) in children. However, the increase in risk of bronchial obstruction resulting from other factors, such as building dampness, was moderately to markedly higher in homes with ventilation rates below 0.5 air changes per hour (ach). In other words, having low ventilation rates increased the health risks from some building conditions (e.g., dampness) associated with indoor pollutant emissions. Bornehag et al. (2005) studied 390 single-family homes and found that children in homes with very low ventilation rates (0.05 to 0.24 ach) had twice as many allergic symptoms compared to those in homes with high ventilation rates (0.44 to 1.44 ach). However, Emenius et al. (2004) found that the risk of recurrent wheezing in children was not different for houses with measured air exchange rates above and below 0.5 ach. Another residential study (Norback et al. 1995) found that the risk of having asthma symptoms was increased in homes with higher indoor carbon dioxide concentrations, which indicate less ventilation per person. There is also indirect evidence that ventilation rates of homes affect health by modifying the indoor concentrations of a broad range of indoor-generated air pollutants. Because exposures to some of these air pollutants (e.g., environmental tobacco smoke, formaldehyde) have been linked with adverse health (California EPA 1997; DHHS 2006; Mendell 2006; WHO 2002), it is likely that increased home ventilation rates would reduce the associated health effects.

Indoor concentrations of some outdoor air pollutants can be increased with an increased ventilation rate. Ozone concentrations may be the one of most concern: higher outdoor air ozone concentrations are associated with adverse respiratory and irritation effects and several other health effects (Hubbell et al. 2005). Increases in ventilation rates can also increase indoor concentrations of, and exposures to, outdoor air respirable particles, while reducing exposures to indoor-generated particles. Higher outdoor particle concentrations are associated with a broad range of adverse health effects (Pope and Dockery 2006). If incoming outdoor air is filtered to remove most particles, the influence of ventilation rate on indoor particle concentrations can be small (Fisk et al. 2002).

Increases in ventilation rate reduce indoor humidity when outdoor air is dry but increase indoor humidity when outdoor air humidity is high and the building mechanical systems also do not dehumidify sufficiently to counteract the effects of increased moisture entry. Some studies have found that levels of house dust mites or allergens from mites, which are associated with allergy and asthma symptoms, decrease with higher ventilation rates, but findings have not been consistent (Fisk 2009). Where increased ventilation results in high indoor humidity, dust mite allergen levels and the risk of indoor mold growth/colonization problems also increase.

Overall, increases in ventilation rate diminish exposures to various indoor-generated air pollutants and might increase exposures to some outdoor air pollutants. On balance, the scientific literature points to improvements in health with increased ventilation rates. Appropriate air-cleaning methods should be used to remove excessive pollutants in the outdoor ventilation air, as required in ASHRAE *Standards* 62.1 and 61.2.

CHAPTER 11

AIR CONTAMINANTS

CLASSES OF AIR CONTAMINANTS 11.1
PARTICULATE CONTAMINANTS 11.2
Particulate Matter 11.2
GASEOUS CONTAMINANTS 11.8
Volatile Organic Compounds 11.13
Semivolatile Organic Compounds 11.15
Inorganic Gases 11.15
AIR CONTAMINANTS BY SOURCE 11.16
Outdoor Air Contaminants 11.16
Industrial Air Contaminants 11.17
Commercial, Institutional, and Residential Indoor Air Contaminants 11.18
Flammable Gases and Vapors 11.20
Combustible Dusts 11.20
Radioactive Air Contaminants 11.21
Soil Gases 11.22

AIR contamination is a concern for ventilation engineers when it causes problems for building occupants. Engineers need to understand the vocabulary used by the air sampling and building air cleaning industry. This chapter focuses on the types and levels of air contaminants that might enter ventilation systems or be found as indoor contaminants. Industrial contaminants are included only for special cases. Because it is not a building air concern, the effects of refrigerants on the atmosphere are not included in this chapter; see Chapter 29 for discussion of this topic.

Air is composed mainly of gases. The major gaseous components of clean, dry air near sea level are approximately 21% oxygen, 78% nitrogen, 1% argon, and 0.04% carbon dioxide. Normal outdoor air contains varying amounts of other materials (permanent atmospheric impurities) from natural processes such as wind erosion, sea spray evaporation, volcanic eruption, and metabolism or decay of organic matter. The concentration of permanent atmospheric impurities varies, but is usually lower than that of anthropogenic (i.e., caused by human activities) air contaminants.

Anthropogenic outdoor air contaminants are many and varied, originating from numerous types of human activity. Electric-power-generating plants, various modes of transportation, industrial processes, mining and smelting, construction, and agriculture generate large amounts of contaminants. These outdoor air contaminants can also be transmitted to the indoor environment. In addition, the indoor environment can exhibit a wide variety of local contaminants, both natural and anthropogenic.

Contaminants that present particular problems in the indoor environment include allergens (e.g., dust mite or cat antigen), tobacco smoke, radon, and formaldehyde.

Air composition may be changed accidentally or deliberately. In sewers, sewage treatment plants, agricultural silos, sealed storage vaults, tunnels, and mines, the oxygen content of air can become so low that people cannot remain conscious or survive. Concentrations of people in confined spaces (theaters, survival shelters, submarines) require that carbon dioxide given off by normal respiratory functions be removed and replaced with oxygen. Pilots of high-altitude aircraft, breathing at greatly reduced pressure, require systems that increase oxygen concentration. Conversely, for divers working at extreme depths, it is common to increase the percentage of helium in the atmosphere and reduce nitrogen and sometimes oxygen concentrations.

At atmospheric pressure, oxygen concentrations less than 12% or carbon dioxide concentrations greater than 5% are dangerous, even for short periods. Lesser deviations from normal composition can be hazardous under prolonged exposures. Chapter 10 further details environmental health issues.

Although lack of oxygen can be a danger in confined spaces, it is unlikely ever to be a problem in naturally and mechanically ventilated buildings. Although the amount of oxygen consumed approximates the amount of carbon dioxide produced by respiration, the level of oxygen in the air is so much greater than that of carbon dioxide to start with that there is effectively no change in oxygen content between air intake and exhaust.

1. CLASSES OF AIR CONTAMINANTS

Air contaminants are generally classified as either particles or gases. Particles dispersed in air are also known as **aerosols**. In common usage, the terms *aerosol*, *airborne particle*, and *particulate air contaminant* are interchangeable. The distinction between particles and gases is important when determining removal strategies and equipment. Although the motion of particles is described using the same equations used to describe gas movement, even the smallest particles are much larger and more massive than individual gas molecules, and have a much lower diffusion rate. Conversely, particles are typically present in much fewer numbers than even trace levels of contaminant gases.

The **particulate** class covers a vast range of particle sizes, from dust large enough to be visible to the eye to submicroscopic particles that elude most filters. Particles may be liquid, solid, or have a solid core surrounded by liquid. The following traditional particulate contaminant classifications arise in various situations, and overlap. They are all still in common use.

- **Dusts**, **fumes**, and **smokes** are mostly solid particulate matter, although smoke often contains liquid particles.
- **Mists**, **fogs**, and **smogs** are mostly suspended liquid particles smaller than those in dusts, fumes, and smokes.
- **Bioaerosols** include primarily intact and fragmentary viruses, bacteria, fungal spores, and plant and animal allergens; their primary effect is related to their biological origin. Common indoor particulate allergens (dust mite allergen, cat dander, house dust, etc.) and endotoxins are included in the bioaerosol class.
- Particulate contaminants may be defined by their size, such as **coarse**, **fine**, or **ultrafine**; **visible** or **invisible**; or **macroscopic**, **microscopic**, or **submicroscopic**.
- Particles may be described using terms that relate to their interaction with the human respiratory system, such as **inhalable** and **respirable**

The **gaseous** class covers chemical contaminants that can exist as free molecules or atoms in air. Molecules and atoms are smaller than particles and may behave differently as a result. This class covers two important subclasses:

The preparation of this chapter is assigned to TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment, in conjunction with TC 2.4, Particulate Air Contaminants and Particulate Contaminant Removal Equipment.

Copyright © 2021, ASHRAE

Licensed for single user. © 2021 ASHRAE, Inc.

- **Gases**, which are naturally gaseous under ambient indoor or outdoor conditions (i.e., their boiling point is less than ambient temperature at ambient pressure)
- **Vapors**, which are normally solid or liquid under ambient indoor or outdoor conditions (i.e., their boiling point is greater than ambient temperature at ambient pressure), but which evaporate readily

Through evaporation, liquids change into vapors and mix with the surrounding atmosphere. Like gases, they are formless fluids that expand to occupy the space or enclosure in which they are confined.

Air contaminants can also be classified according to their sources; properties; or the health, safety, and engineering issues faced by people exposed to them. Any of these can form a convenient classification system because they allow grouping of applicable standards, guidelines, and control strategies. Most such special classes include both particulate and gaseous contaminants.

This chapter also covers background information for selected special air contaminant classes (Chapter 10 deals with applicable indoor health and comfort regulations).

- Outdoor air contaminants
- Industrial air contaminants
- Nonindustrial indoor air contaminants and indoor air quality
- Flammable gases and vapors
- Combustible dusts
- Radioactive contaminants
- Soil gases

In the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*, Chapter 29 discusses particulate air contaminant removal, and Chapter 30 covers industrial air cleaning. Chapter 46 in the 2019 *ASHRAE Handbook—HVAC Applications* deals with gaseous contaminant removal.

2. PARTICULATE CONTAMINANTS

2.1 PARTICULATE MATTER

Airborne particulate contamination ranges from dense clouds of desert dust storms to completely invisible and dilute cleanroom particles. It may be anthropogenic or completely natural. It is often a mixture of many different components from several different sources. A much more extensive discussion of particulate contamination is available from the U.S. Environmental Protection Agency (EPA 2016a).

Particles occur in a variety of different shapes, including spherical, irregular, and fibers, which are defined as particles with aspect ratio (length-to-width ratio) greater than 3. In describing particle size ranges, *size* is the diameter of an assumed spherical particle.

Solid Particles

Dusts are solid particles projected into the air by natural forces such as wind, volcanic eruption, or earthquakes, or by mechanical processes such as crushing, grinding, demolition, blasting, drilling, shoveling, screening, and sweeping. Some of these forces produce dusts by reducing larger masses, whereas others disperse materials that have already been reduced. Particles are not considered to be dust unless they are smaller than about 100 μm. Dusts can be mineral, such as rock, metal, or clay; vegetable, such as grain, flour, wood, cotton, or pollen; or animal, including wool, hair, silk, feathers, and leather. *Dust* is also used as a catch-all term (house dust, for example) that can have broad meaning.

Fumes are solid particles formed by condensation of vapors of solid materials. Metallic fumes are generated from molten metals and usually occur as oxides because of the highly reactive nature of finely divided matter. Fumes can also be formed by sublimation, distillation, or chemical reaction. Such processes create submicrometre airborne primary particles that may agglomerate into larger particle (1 to 2 μm) clusters if aged at high concentration.

Bioaerosols are airborne biological materials, including viruses and intact and fragmentary bacteria, pollen, fungi, and bacterial and fungal spores. Individual **viruses (virions)** typically range in size from 0.02 to 0.4 μm, although filioviruses (e.g., ebola) may be longer than 1 μm. Viruses usually occur as aggregates (droplet nuclei) and are associated with sputum or saliva. Therefore, in air they generally appear to be much larger than their true size. Most individual **bacteria** range between 0.4 and 5 μm and may be found singly or as aggregates. Intact individual **fungal** and **bacterial** spores are usually 2 to 10 μm, whereas **pollen** grains are 10 to 100 μm, with many common varieties in the 20 to 40 μm range. The size range of **allergens** varies widely: the allergenic molecule is very small, but the source of the allergen (mite feces or cat dander) may be quite large. See the section on Bioaerosols for more detailed discussion.

Liquid Particles

Mists are aggregations of small airborne droplets of materials that are ordinarily liquid at normal temperatures and pressure. They can be formed by atomizing, spraying, mixing, violent chemical reactions, evolution of gas from liquid, or dissolved gas escaping when pressure is released.

Fogs are clouds of fine airborne droplets, usually formed by condensation of vapor, which remain airborne longer than mists. Fog nozzles are named for their ability to produce extra-fine droplets, as compared with mists from ordinary spray devices. Many droplets in fogs or clouds are microscopic and submicroscopic and serve as a transition stage between larger mists and vapors. The volatile nature of most liquids reduces the size of their airborne droplets from the mist to the fog range and eventually to the vapor phase, until the air becomes saturated with that liquid. If solid material is suspended or dissolved in the liquid droplet, it remains in the air as particulate contamination. For example, sea spray evaporates fairly rapidly, generating a large number of fine salt particles that remain suspended in the atmosphere.

Complex Particles

Smokes are small solid and/or liquid particles produced by incomplete combustion of organic substances such as tobacco, wood, coal, oil, and other carbonaceous materials. The term *smoke* is applied to a mixture of solid, liquid, and gaseous products, although technical literature distinguishes between such components as soot or carbon particles, fly ash, cinders, tarry matter, unburned gases, and gaseous combustion products. Smoke particles vary in size, the smallest being much less than 1 μm in diameter. The average is often in the range of 0.1 to 0.3 μm.

Environmental tobacco smoke (ETS) consists of a suspension of 0.01 to 1.0 μm (mass median diameter of 0.3 μm) solid and liquid particles that form as the superheated vapors leaving burning tobacco condense, agglomerate into larger particles, and age. Numerous gaseous contaminants are also produced, including carbon monoxide.

Smog commonly refers to air pollution; it implies an airborne mixture of smoke particles, mists, and fog droplets of such concentration and composition as to impair visibility, in addition to being irritating or harmful. The composition varies among different locations and at different times. The term is often applied to haze caused by a sunlight-induced photochemical reaction involving materials in automobile exhausts. Smog is often associated with temperature inversions in the atmosphere that prevent normal dispersion of contaminants.

Sizes of Airborne Particles

Particle size can be defined in several different ways. These depend, for example, on the source or method of generation, visibility, effects, or measurement instrument. Ambient atmospheric

Licensed for single user. © 2021 ASHRAE, Inc.

particulate contamination is classified by aerosol scientists and the EPA by source mode, with common usage now recognizing three primary modes: coarse, fine, and ultrafine.

Coarse-mode aerosol particles are largest, and are generally formed by mechanical breaking up of solids. They generally have a minimum size of 1 to 3 μm (EPA 2009a). Coarse particles also include bioaerosols such as mold spores, pollen, animal dander, and dust mite particles that can affect the immune system. Coarse-mode particles are predominantly primary, natural, and chemically inert. Road dust is a good example. Chemically, coarse particles tend to contain crustal material components such as silicon compounds, iron, aluminum, sea salt, and vegetative particles.

Fine-mode particles are generally secondary particles formed from chemical reactions or condensing gases. They have a maximum size of about 1 to 3 μm. Fine particles are usually more chemically complex than coarse-mode particles and result from human activity, particularly combustion. Smoke is a good example. Chemically, fine aerosols typically include sulfates, organics, ammonium, nitrates, carbon, lead, and some trace constituents. The modes overlap, and their definitions are not precise.

Recently, there has been increased interest in even smaller contaminants, known as **ultrafine**-mode particles. Ultrafines have a maximum size of 0.1 μm (100 nm) (EPA 2009a). They are complex particles for which the biggest source is reaction of gases with other particles. They also form as a result of degradation of larger particles. Natural sources include volcanic eruptions, ocean spray, and smoke from wildfires. Sources involving human activity include tobacco smoke, burning of fossil fuels, and emissions from cooking and office machines. Engineered ultrafines, often referred to as **nanoparticles**, have a variety of applications, particularly in the medical field (Moghini et al. 2005). The U.S. National Nanotechnology Initiative (NNI 2008) uses the same size definition for nanoparticles as given above for ultrafine particles. Figure 1 shows a typical distribution, including the chemical species present in each of the three modes.

The size of a particle determines where in the human respiratory system particles are deposited, and various samplers collect particles that penetrate more or less deeply into the lungs. Figure 2 shows the relative deposition efficiencies of various sizes of particles in the human nasal and respiratory systems. The **inhalable mass** is made up of particles that may deposit anywhere in the respiratory system, and is represented by a sample with a median cut point of 100 μm. Most of the inhalable mass is captured in the nasal passages. The **thoracic particle mass** is the fraction that can penetrate to the respiratory airways and is represented by a sample with a median cut point of 10 μm (PM_{10}). The **respirable particle mass** is the fraction that can penetrate to the gas-exchange region of the lungs, which ACGIH (1989) defines as having a median cut point of 4 μm. The EPA no longer uses the term *respirable*. Their current concern is with particles having a median cut point of 2.5 μm ($PM_{2.5}$) (this definition includes both fine and ultrafine particles as discussed above), and with smaller particles such as PM_1.

Particles differ in density, and may be irregular in shape. It is useful to characterize mixed aerosol size in terms of some standard particle. The **aerodynamic (equivalent) diameter** of a particle, defined as the diameter of a unit-density sphere having the same gravitational settling velocity as the particle in question (Willeke and Baron 1993), is commonly used as the standard particle size. Samplers that fractionate particles based on their inertial properties, such as impactors and cyclones, naturally produce results as functions of the aerodynamic diameters. Samplers that use other sizing principles, such as optical particle counters, must be calibrated to give aerodynamic diameter.

The tendency of particles to settle on surfaces is of interest. Figure 3 shows the sizes of typical indoor airborne solid and liquid particles. Particles smaller than 0.1 μm behave like gas molecules, exhibiting irregular motion from collisions with air molecules and having no measurable settling velocity. Particles in the range from 0.1 to 1 μm have calculable settling velocities, but they are so low that settling is usually negligible, because normal air currents counteract any settling. By number, over 99.9% of the particles in a typical atmosphere are below 1 μm (i.e., fewer than 1 particle in every 1000 is larger than 1 μm). Particles between 1 and 10 μm settle in still air at constant and appreciable velocity. However, normal air currents keep them in suspension for appreciable periods. Particles larger than 10 μm settle fairly rapidly and can be found suspended in air only near their source or under strong wind conditions. Exceptions are lint and other light, fibrous materials, such as portions of some weed seeds, which remain suspended longer because their aerodynamic behavior is similar to that of smaller particles (they have aerodynamic diameters smaller than their physical dimensions suggest.)

Table 1 shows settling times for various types of particles. Most individual particles 10 μm or larger are visible to the naked eye under favorable conditions of lighting and contrast. Smaller particles are visible only in high concentrations. Cigarette smoke (with an average particle size less than 0.5 μm) and clouds are common examples. Direct fallout in the vicinity of the dispersing stack or flue and other nuisance problems of air pollution involve larger particles.

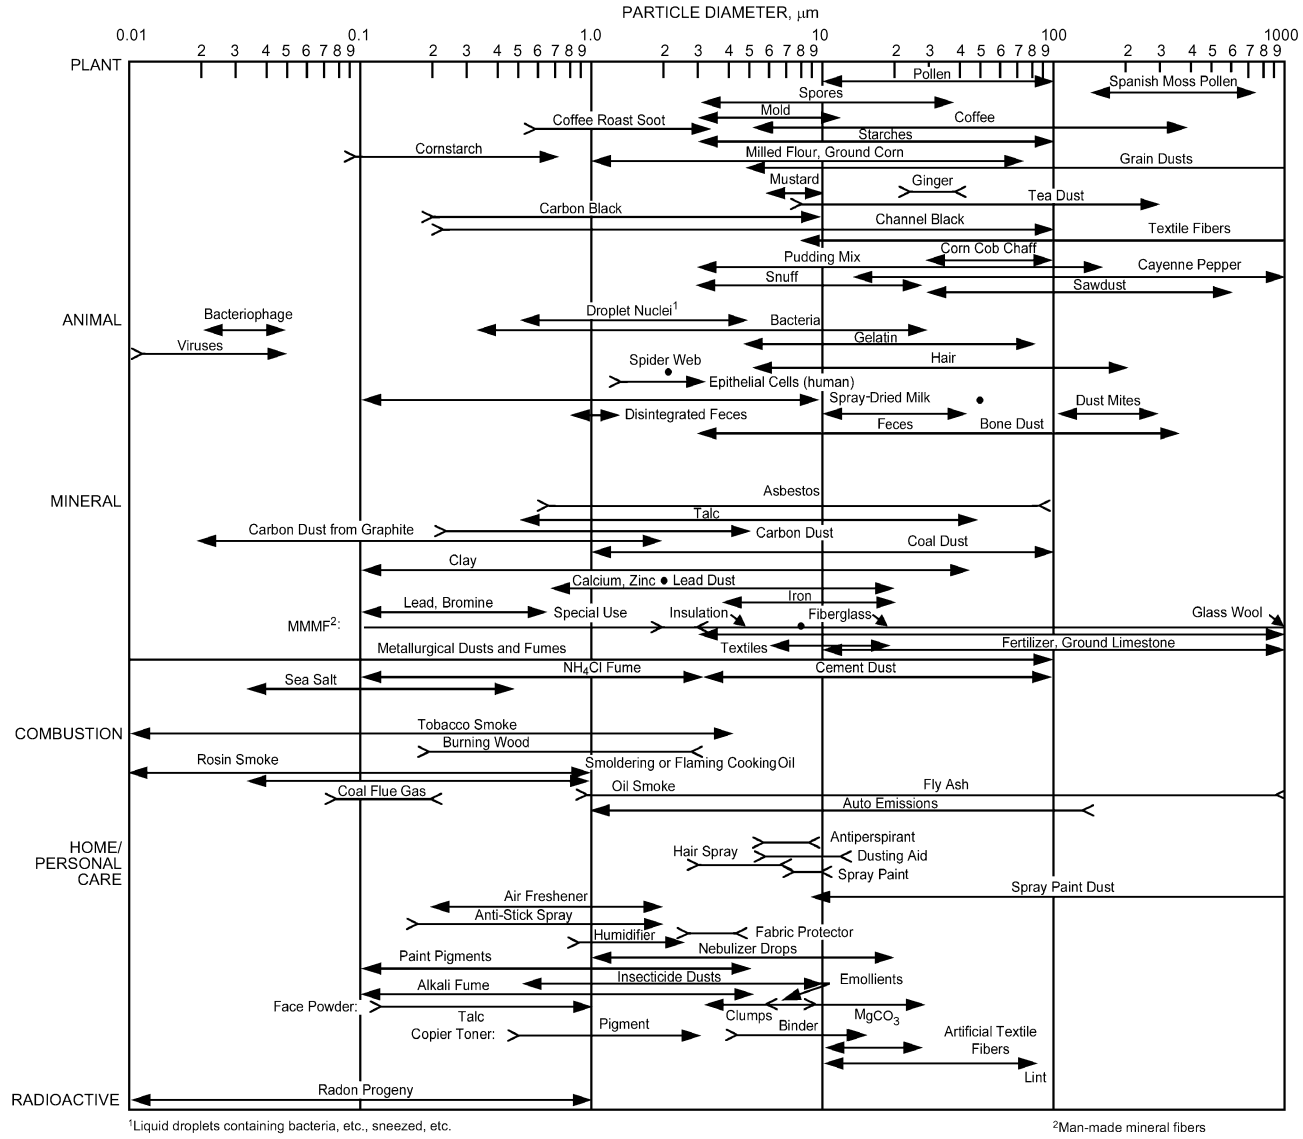

Fig. 3 Sizes of Indoor Particles
(Owen et al. 1992)

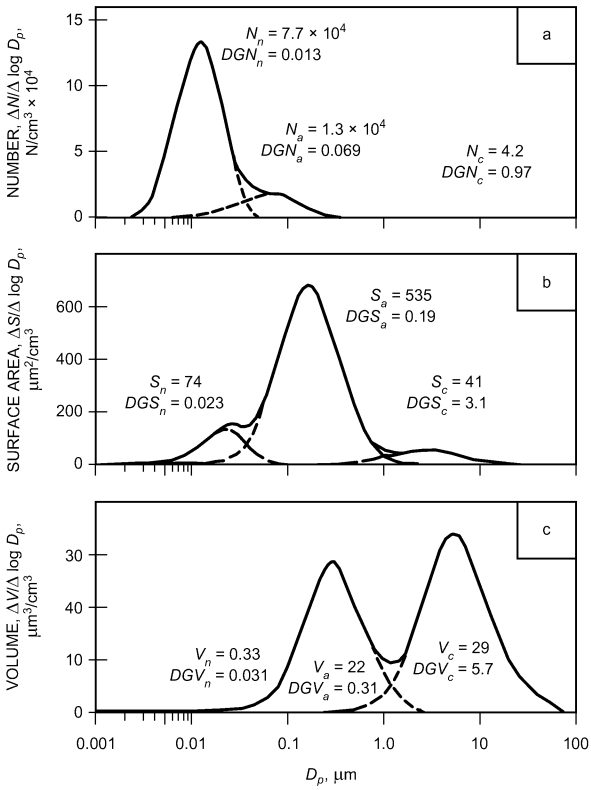
Table 1 Approximate Particle Sizes and Time to Settle 1 m

Type of Particle	Diameter, μm	Settling Time
Human hair	100 to 150	3 to 1 s
Skin flakes	20 to 40	80 to 20 s
Observable dust in air	>10	<5.5 min
Common pollens	15 to 25	2 to 1 min
Mite allergens	10 to 20	6 to 1 min
Common spores	2 to 10	128 to 6 min
Bacteria	1 to 5	475 to 21 min
Cat dander	1 to 5	475 to 21 min
Tobacco smoke	0.1 to 1	13 days to 8 h
Metal and organic fumes	<0.1 to 1	>13 days to 8 h
Cell debris	0.01 to 1	171 days to 8 h
Viruses	<0.1	>13 days

Note: Spores, bacteria, and virus sizes are for the typical complete unit. As entrained in the air, they may be smaller (fragments) or larger (attached to debris, enclosed in sputum, etc.)
Based on information obtained from J.D. Spengler, Harvard School of Public Health, 1982.

Table 2 Relation of Screen Mesh to Sieve Opening Size

U.S. Standard sieve mesh	400	325	200	140	100	60	35	18
Nominal sieve opening, μm	37	44	74	105	149	250	500	1000



Source: Excerpted from ASTM *Standard* E11-15.

Smaller particles, as well as mists, fogs, and fumes, remain in suspension longer. In this size range, meteorology and topography are more important than physical characteristics of the particles. Because settling velocities are small, the atmosphere's ability to disperse these small particles depends largely on local weather conditions. Comparison is often made to screen sizes used for grading useful industrial dusts and granular materials. Table 2 shows the relationship of U.S. standard sieve mesh to particle size in micrometers. Particles above 40 μm are known as the screen sizes, and those below are known as the subscreen or microscopic sizes.

Particle Size Distribution

The particle size distribution in any sample can be expressed in several different ways. Figure 4 shows particle count data for typical

Licensed for single user. © 2021 ASHRAE, Inc.

Data are plotted by particle number *N* (plot A), surface area *S* (plot B), and volume *V* (plot C). D_p is particle diameter in microns. Legends show geometric mean diameters (*DG*) for each distribution, and particle number, surface area, or volume in mode.

Fig. 4 Typical Urban Outdoor Distributions of Ultrafine or Nuclei (n) Particles, Fine or Accumulation (a) Particles, and Coarse (c) Particles
(Whitby 1978)

coarse and fine atmospheric contamination plotted to show particle number, total particle surface area, and total particle volume as a function of particle size.

Note the differences between the three curves. Figure 4 demonstrates that particles 0.1 μm or less in diameter typically make up about 80% of the number of particles in the atmosphere but contribute only about 1% of the volume or mass. Also, 0.1% of the number of particles larger than 1 μm typically carry 70% of the total mass, which is the direct result of the mass of a spherical particle increasing as the cube of its diameter. Although most of the mass is contributed by intermediate and larger particles, over 80% of the area (staining) contamination is supplied by particles less than 1 μm in diameter, which is in the center of the respirable particle size range and is the size most likely to remain in the lungs (see Figure 2 and Chapter 10). Of possible concern to the HVAC industry is the fact that most of the staining effect on ceilings, walls, windows, and light fixtures results from particles less than 1 μm in diameter. Fouling of heat transfer devices and rotating equipment involves particles in this size range and larger. Suspended particles in urban air are predominantly smaller than 1 μm (aerodynamic diameter) and have a distribution that is approximately log-normal.

Units of Measurement

The quantity of particulate matter in the air can be determined as a mass or particle count in a given volume of air. Mass units are milligrams per cubic metre of air sampled (mg/m^3) or micrograms per cubic metre of air sampled (μg/m^3); 1 mg/m^3 = 1000 μg/m^3. Particle counts are usually quoted for volumes of 0.1 ft^3, 1 ft^3, 1 L, or 1 m^3 and are specified for a given range of particle diameter.

Harmful Effects of Particulate Contaminants

Particulate contaminants can be damaging to people, the buildings in which they live and work, and materials and artifacts in these buildings.

Effects on People. Harmful effects of nonviable particles on people include toxicity, irritation, and odor. Effects of viable particles are covered in the section on Bioaerosols and in Chapter 10.

Dusts produced in industrial processes can be highly toxic (see Chapter 10). Most nonviable particles encountered outdoors and in commercial and residential buildings are of lower toxicity. Their impact depends on particle size and amount present. Larger coarse and fine particles trapped before reaching the lungs are likely to cause irritation if present in sufficient quantity. Smaller fine and ultrafine particles that reach the lungs are more of an issue. There have been concerns for many years about the long-term effects on the lungs of exposure to particles, but the first support for an association between airborne coarse particles and incidence of asthma and hospital admissions for respiratory problems did not come until the 1990s (Pope 1991). Other studies have shown that chronic exposure to fine particles can affect both the heart and lungs (Pope et al. 2002), and identified fine particles as a priority chronic hazard in U.S. homes (Logue et al. 2011). Ultrafine particles, which have much higher number concentrations and surface areas than fine particles and can adsorb gaseous contaminants, may also be health issues (Delfino et al. 2005; Soutas et al. 2005). More information on health effects of particulate matter can be found in Chapter 10.

Particulate contaminants are not odorous in themselves but can become so by adsorbing odorous gaseous contaminants such as nitrogen and sulfur oxides from combustion processes. Such particles can be trapped by HVAC filters and may release the odor later on.

Effects on Materials. Damage depends on the size of the particles, with larger particles having the potential for settling on and abrading materials, and smaller particles having the potential for soiling both horizontal and vertical surfaces. Both size ranges are of concern for HVAC components, and their impacts can be reduced by using filters. Finishes and furnishings in occupied buildings can require more frequent maintenance if soiling is not effectively controlled. Artworks and artifacts in galleries and museums can be permanently damaged by exposure to both abrasive and soiling particles; for details, see Chapter 23 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Measurement of Airborne Particles

Suitable methods for determining the quantity of particulate matter in the air vary, depending on the amount present and on the size of particles involved. **Direct gravimetric measurement**, in which a dusty air sample is drawn through a preweighed filter, is a common technique in industrial workplaces that often contain significant numbers of large particles. If the total airstream is drawn through the test filter, the sample is known as the **total mass**; if a size-selective inlet is used on the filter, the sample is characterized by the inlet used ($PM_{2.5}$, PM_{10}, respirable, etc.). Gravimetric methods have the advantage of providing an integrated sample (over the sample duration) and of providing a direct measure of the mass concentration (mass/volume). In general, gravimetric methods are not real-time, although some innovative samplers use secondary methods (e.g., beta attenuation, crystal vibration frequency changes) to infer mass on a real-time basis. Further, gravimetric methods require increasing test effort (sample duration and balance quality) as the mass concentration drops toward office and indoor air levels.

Normal daily activities of individuals cause higher personal exposures to both particles and gas contaminants than would be

Licensed for single user. © 2021 ASHRAE, Inc.

expected from measurements of undisturbed air. Personal activities frequently bring individuals close to air contaminant sources, and also generate particles. Sampling near a person requires special care because the degree of exposure also depends on particle transport as air flows around the body because of convective forces, air turbulence, and obstructions nearby (Rodes and Thornburg 2004).

Optical particle counters (OPCs) are widely used and likely to become more so. They are very convenient and provide real-time, size-selective data. Individual aerosol particles are illuminated with a bright light as they singly pass through the OPC viewing volume. Each particle scatters light, which is collected to produce a voltage pulse in the detector. The pulse size is proportional to the particle size, and the electronics of the OPC assign counts to size ranges based on the pulse size. ASHRAE *Standard* 52.2 defines a laboratory method for assessing the performance of media filters using an OPC to measure particle counts up- and downstream of the filter in 12 size ranges between 0.3 and 10 μm. Filters tested are reported with their **minimum efficiency reporting value (MERV)** number based on the count data. It is important to sample isokinetically in fast-moving airstreams, such as found in air ducts. This involves sizing the OPC sampling inlet so that the speed of sampled air entering the device is the same as that of air moving past the OPC. If this is not done, the OPC samples inaccurately, capturing too few particles when sampling speed is greater than surrounding air speed, and too many when sampling speed is less than that of the surrounding air.

Counters are also used to test cleanrooms for compliance with the U.S. General Services Administration's (GSA) *Federal Standard* 209E and ISO *Standard* 14644-1. Cleanrooms are defined in terms of the number of particles in certain size ranges that they contain; for more information, see Chapter 18 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Modern OPCs use laser light scattering to continuously count and size airborne particles and, depending on design, can detect particles down to 0.1 μm (ASTM *Standard* F50). Like all aerosol instruments, OPCs should be used with awareness of their limitations. They report particle size from a calibration curve that was developed from a particle having particular optical properties. Actual ambient aerosol particle size is usually close to that indicated by an OPC, but significant errors are possible. Further, many OPCs were developed for cleanroom applications and can become overloaded in other applications. In general, they do not inform the user when they are out of range.

A **condensation nucleus counter (CNC)** can count particles to below 0.01 μm. These particles, present in great numbers in the atmosphere, serve as nuclei for condensation of water vapor (Scala 1963). CNCs provide total particle numbers, and cannot directly provide particle sizing information.

Another indirect method measures the **optical density** of the collected dust, based on the projected area of the particles. Dust particles can be sized with graduated scales or optical comparisons using a standard microscope. The lower limit for sizing with the light-field microscope is approximately 0.9 μm, depending on the vision of the observer, dust color, and available contrast. This size can be reduced to about 0.4 μm by using oil-immersion objective techniques. Dark-field microscopic techniques reveal particles smaller than these, to a limit of approximately 0.1 μm. Smaller submicroscopic dusts can be sized and compared with the aid of an electron microscope.

Other sizing techniques may take into account velocity of samplings in calibrated devices and actual settlement measurements in laboratory equipment. The electron microscope and sampling instruments such as the cascade impactor have been successful in sizing particulates, including fogs and mists. Each method of measuring particle size distribution gives a different value for the same size particle, because different properties are actually measured. For example, a microscopic technique may measure longest dimension, whereas impactor results are based on aerodynamic behavior (ACGIH 2001).

Chemical analysis of particles follows protocols for analysis of any solid material. At industrial concentrations, adequate samples can be obtained from ducts and dust collectors. Because larger particles settle faster than smaller particles, the size and nature of deposited particles often change as suspended particles move away from a source. For instance, near the inlet of an outdoor air intake, deposited particles will probably be larger and have a coarse composition (e.g., road dust might predominate), whereas further into the duct, fine-mode aerosols would predominate (e.g., condensed oil fume and soot). At the lower concentrations of workplaces, samples are usually collected onto filters, and the filter deposit is analyzed. The filter material must be chosen to not interfere with the analysis. After sample preparation, analysis methods for gaseous contaminant analysis generally apply.

Typical Particle Levels

Particle counters, which detect particles larger than about 0.1 μm, indicate that the number of suspended particles is enormous. A room with heavy cigarette smoke has a particle concentration of 10^{12} particles per cubic metre. Even clean air typically contains over 35×10^6 particles/m^3. If smaller particles detectable by other means, such as an electron microscope or condensation nucleus counter, are also included, the total particle concentration would be greater than these concentrations by a factor of 10 to 100. Ultrafine particles have been widely found at concentrations of 20×10^9 to 40×10^9 per cubic metre in both indoor and outdoor air.

Much of the published particle data uses mass concentration rather than number concentration, because the EPA outdoor limits are expressed in these units (see Table 12). Typical daytime average levels of outdoor PM_{10} and $PM_{2.5}$ in school or residential areas may be 10 to 30 μg/m^3 (Fromme et al. 2008; Williams et al. 2000), and $PM_{2.5}$ in heavy traffic areas in large cities can be >100 μg/m^3 (Cassidy et al. 2007; Han et al. 2005). In indoor environments with few internal sources, such as offices, indoor concentrations in both size ranges tend to be smaller than outdoors because of HVAC filters. However, in schools, where activity levels are higher and indoor sources are present, indoor PM_{10} and $PM_{2.5}$ may be higher than outdoors (Fromme et al. 2008).

Indoor particle levels in buildings are influenced by the number of people and their activities, building materials and construction, outdoor conditions, ventilation rate, and the air-conditioning and filtration system. Wallace (1996) reviewed the effect of outdoor particle penetration and activities on indoor concentrations, and Riley et al. (2002) discussed the influence of air exchange rates and filtration on indoor concentrations in residential and commercial buildings. ASHRAE research project RP-1281 investigated factors affecting the penetration of fine and ultrafine particles into nonresidential buildings (Facciola et al. 2006). For further information, see the section on Commercial, Institutional, and Residential Indoor Air Contaminants.

Bioaerosols

Bioaerosol refers to any airborne biological (generally microscopic) particulate matter. Though often thought of as originating as microorganisms (fungi, bacteria, viruses, protozoa, algae), bioaerosols may also be derived from plants (pollen and plant fragments) and animals (hair, dander, and saliva from dogs and cats; dust mites). In addition to the intact organisms (e.g., bacteria), their parts (fungal spores and fragments), components (endotoxins, allergens), and products (dust mite antigen-containing fecal pellets and fungal mycotoxins) may be included in the definition. The antigen or toxin to which the body reacts may be quite small; only trace amounts are required for many allergic or toxic reactions. Public interest has focused on airborne microorganisms responsible for diseases and

Licensed for single user. © 2021 ASHRAE, Inc.

infections, primarily bacteria and viruses. These are discussed in more detail in Chapter 10, including sources, transmission and health effects.

Bioaerosols are universally present in both indoor and outdoor environments. Although the organisms that are sources of bioaerosols are living, reproducing organisms, bioaerosols themselves do not have to be alive to cause allergic, toxic, or inflammatory responses. In fact, as little as 1 to 10% of outdoor bioaerosol is thought to be viable (Jaenicke 1998; Tong and Lighthart 1999). Furthermore, fragments of bioaerosols may be transported while attached to inert particles, and may be important from an exposure standpoint.

Problems of concern to engineers occur when microorganisms grow and reproduce indoors, or when large amounts of bioaerosol enter a building from outdoors. Buildings are not sterile, nor are they meant to be. The presence of bacteria and fungi outdoors in soil, water, and atmospheric habitats is normal. For example, spores of the fungus *Cladosporium* are commonly found on leaves and dead vegetation and are almost always found in outdoor air samples. Often, they are found in variable numbers in indoor air, depending on the amount of outdoor air that infiltrates into interior spaces or is brought in by the HVAC system. Outdoor microorganisms and pollen can also enter on shoes and clothing and be transferred to other surfaces in buildings. Through infiltration, pollens can be quite problematic indoors, often depending on the season. Pollens discharged by weeds, grasses, and trees (Hewson et al. 1967; Jacobson and Morris 1977; Solomon and Mathews 1978) can cause hay fever. Bioaerosols have properties of special interest to air-cleaning equipment designers (see Chapter 29 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*).

Some bioaerosols originate indoors. Many allergens, such as cat, dog, and dust mite allergens, either originate indoors or have indoor reservoirs (e.g., bedding and fleecy materials). Much attention has been given to fungi, which include yeasts, molds (filamentous fungi), and mildews, as well as large mushrooms, puffballs, and bracket fungi. All fungi depend on external sources of organic material for both energy requirements and carbon skeletons, but very small quantities can be sufficient. Thus, they increase in number when supplied with a suitable food source such as very small quantities of dirt/dust, paper, or wood. Sufficient nutrients are almost always readily available in buildings. For growth to occur, sufficient water must also be available in the material. Adequate moisture content of a material may be attained when the relative humidity is high (typically, the equilibrium relative humidity of a porous material with the surrounding air is greater than 60%), on water incursion from a roof leak or condensation, or when water spills. Note that controlling humidity in a space per se is not sufficient to limit fungal growth; the moisture content of the substrate material must be controlled. Some species of mold that often grow on water-damaged building materials are listed in Table 3.

Mycotoxins are secondary metabolites produced by some filamentous fungi, Some are very toxic (e.g., aflatoxin) and some are beneficial (e.g., penicillin). There are hundreds of different mycotoxins, and more are being identified all the time. Mycotoxins can cause disease and death in humans and other animals, primarily when consumed in foods. However, inhalation exposure of fungal spores and fragments containing mycotoxins has been raised as a potential concern as a bioaerosol contaminant.

Bacteria are much simpler organisms than fungi, and generally require more water for growth, often growing in liquids or periodically wetted surfaces. Whereas fungi actively release spores into the environment from contaminated surfaces, bacteria are generally aerosolized by reentrainment of the water in which they are growing. Cooling towers, evaporative condensers, and domestic water service systems all provide water and nutrients for amplification of bacteria such as *Legionella pneumophila*. Growth of bacterial populations to excessive concentrations is generally associated with inadequate preventive maintenance or leaks creating standing water. *Legionella* is well studied, and ASHRAE *Standard* 188-2015 discusses its risk management.

Table 3 Common Molds on Water-Damaged Building Materials

Mold Species	Mold Species
Alternaria alternata	*Memnoniella echinata*
Aspergillus sydowii	*Paecilomyces variotii*
Aspergillus versicolor	*Penicillium aurantogriseum*
Chaetomium globusum	*Penicillium chrysogenum*
Cladosporium cladosporioides	*Penicillium citrinum*
Cladosporium sphaerospermum	*Penicillium commune*
Eurotium herbariorum	*Stachybotrys chartarum*
Eurotium repens	*Ulocladium chartarum*

Source: Health Canada (2004).

Drain pans and cooling coils may also be sources of bacteria. Growth can occur in the water and the organism then can become aerosolized in water droplets. The most common source of bacteria as bioaerosols, especially in closed occupied spaces, may be droplet nuclei caused by actions such as sneezing, or carried on human or animal skin scales.

Endotoxins are components of the cell walls of a fairly large group of bacteria classified as Gram negative (i.e., crystal violet dye, used in a Gram stain test, does not affect their color). Endotoxin exposure has been associated with a number of adverse health effects. Humidifier fever has been associated with inhalation of endotoxins (Teeuw et al. 1994).

Units of Measurement. Microorganisms such as bacteria and molds are usually measured either as total culturable or total countable bioaerosol. **Culturable** (viable) bioaerosols are those that can be grown in a laboratory culture. Results are normally reported as number of colony-forming units (CFU) per unit sample volume (m^3 for air samples), area (cm^2 for surface samples) or mass (g for bulk samples).

Countable bioaerosols (viable plus nonviable) include all particles that can be identified and counted under a microscope. Results are reported as number of particles per unit sample volume, area, or mass.

Allergens are usually expressed as their mass (in ng) per unit volume; endotoxins are expressed as EU or endotoxin units.

Sampling. Sampling when bioaerosols are suspected as a contaminant may include direct plating of observed microbial growth, collection of bulk or surface samples, or air sampling. Surface sampling is useful for bioaerosol detection, because the surface may constitute a long-time duration sampler. The principles of sampling and analysis for bioaerosols are presented in depth by Macher (1999). AIHA (1996) gives assessment guidelines for collecting microbiological particulates.

The same principles that affect collection of an inert particulate aerosol sample also govern air sampling for microorganisms. Air sampling is not likely to yield useful data and information unless the sample collected is representative of exposure, and appropriate control samples are collected. The most representative samples are those collected in breathing zones over the range of aerosol concentrations. Personal sampling (in the breathing zone of a worker) is generally preferable, but area sampling (e.g., on a table) over representative periods is more commonly performed. Some investigators attempt to replicate exposure conditions through disturbance of the environment (semiaggressive sampling), such as occurs when walking on carpets, slamming doors, and opening books or file cabinets.

The sampling method selected affects the measured count. Methods that rely on counting analysis usually report higher concentrations than those that use culturing analysis, because of inclusion of nonviable particles. There is no single, ideal bioaerosol sampler, but rather several complementary techniques that may

Licensed for single user. © 2021 ASHRAE, Inc.

be appropriate in any particular application. Collection directly on **filter paper** is simple and direct, but may dehydrate some organisms and underestimate exposure for live counting techniques. **Glass impingers** are an effective and standard method, but may overestimate exposure because liquid contact and agitation can break clusters into smaller individual organisms, which are then each counted as a separate entity. **Slit-to-agar samplers** may give a more accurate culturable colony count, but do not measure nonculturable organisms or fragments, parts, or components. In general, culture plate impactors, including multiple- and single-stage devices as well as slit-to-agar samplers, are most useful in office environments where low concentrations of bacteria and fungi are expected. Some multihole impactors require application of a positive hole correction factor to the raw counts to compensate for multiple organisms focused aerodynamically and landing in the same place on the media. Because not all microorganisms can grow on the same media, impactors that separate samples must be collected for each. Liquid impingement subculturing allows plating one sample on multiple media. Filter cassette samplers are useful for some hardy microorganisms or components (e.g., endotoxins) and allergen analyses. Filter cassettes can also be used for spore counts.

Nonculture methods for fungal spores and pollen grains generally involve exposing an adhesive-coated glass slide or plate for a specific time period, then counting calibrated areas under the microscope, and calculating the number in a measured volume of air. Measurement methods for pollen are not discussed further here, because data are widely available in the public domain.

Some viruses, bacteria, algae, and protozoa are more difficult to culture than fungi, and air-sampling methodology for these organisms may not be practical. For example, *Legionella* requires special nutrients and conditions for growth, and thus may be difficult to recover from air. To further complicate the issue, not all fungi grow on any one media, so media selection may be important.

Rank-order assessment is used to interpret air-sampling data for microorganisms (Macher 1999). Individual organisms are listed in descending order of abundance for a complainant indoor site and for one or more control locations. The predominance of one or more microbes in the complainant site, but not in the control sites or outdoors, suggests the presence of a source for that organism. An example is shown in Table 4.

Recently, quantitative real-time **polymerase chain reaction (PCR)** (Mullis 1990) testing has been developed for routine diagnosis of specific microorganisms in clinical microbiology laboratories (Espy 2006) and for mold determination in residential and commercial venues. PCR is a molecular technique for multiplying a specific strand of DNA or RNA millions of times by manipulating the chemical nature of the cell. Once multiplied (or amplified), the target DNA can be detected through a variety of methods.

PCR-based methods eliminate the need to culture organisms for detection, and remedy shortcomings of traditional techniques by allowing rapid, sensitive, and specific identification of the pathogens of concern rather than indicator organisms. Traditional culturing can take anywhere from 3 to 7 days, whereas real-time PCR can often be run in 10 to 24 h (Yang and Rothman 2004).

Table 4 Example Case of Airborne Fungi in Building and Outdoor Air

Location	CFU/m^3	Rank Order Taxa
Outdoors	210	*Cladosporium* > *Fusarium* > *Epicoccum* > *Aspergillus*
Complainant office #1	2500	*Tritirachium* > *Aspergillus* > *Cladosporium*
Complainant office #2	3000	*Tritirachium* > *Aspergillus* > *Cladosporium*

Notes: CFU/m^3 = colony-forming units per cubic metre of air. Culture media, for this example, was malt extract agar (ACGIH 1989).

U.S. Environmental Protection Agency (EPA) and Department of Housing and Urban Development (HUD) researchers have developed a metric called the environmental relative moldiness index (ERMI) to objectively describe the home mold burden (Vesper et al. 2007). A DNA-based analysis called mold-specific quantitative PCR (MSQPCR) of 36 molds, including 26 species associated with homes with water damage and 10 found in homes independent of water damage, forms the basis of the ERMI.

Controlling Exposures to Particulate Matter

Control of airborne particulate levels may be achieved by one of four methods:

- Reduction of source emissions
- Capture of emissions at the source using local exhaust
- Dilution using mechanical ventilation
- Removal from ventilation air by filtration

Of these, filtration is of particular importance to HVAC&R. This topic is covered in detail in Chapter 29 in the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

Control of bioaerosols is a complex issue because of their capacity for growth and dispersion. However, in general, particulate removal devices and controls are effective in collecting and removing bioaerosols, including allergens (Foarde et al. 1994). Control may also be achieved by ultraviolet irradiation, as described in Chapter 60 of the 2019 *ASHRAE Handbook—HVAC Applications*.

3. GASEOUS CONTAMINANTS

The terms **gas** and **vapor** are both used to describe the gaseous state of a substance. *Gas* is the correct term for describing any pure substance or mixture that naturally exists in the gaseous state at normal atmospheric conditions. That is, its vapor pressure is greater than ambient pressure at ambient temperature. Examples are oxygen, helium, ammonia, and nitrogen. *Vapor* is used to describe a substance in the gaseous state whose natural state is a liquid or solid at normal atmospheric conditions. The vapor pressure is below ambient pressure at ambient temperature. Examples include benzene, carbon tetrachloride, and water. Differences between the two classes reflect their preferred states:

- For a strong source, the concentration of a gas in air in a confined space can rise above one atmosphere. Thus, even nontoxic gases can be lethal if they completely fill a space, displacing the oxygen necessary for survival.
- Vapors can never exceed their saturated vapor pressure in air. The most familiar example of a vapor is water, with relative humidity expressing the air concentration as a percentage of the saturated vapor pressure.
- Vapors, because their natural state is liquid or solid (low vapor pressure), tend to condense on surfaces and be adsorbed.

Gaseous contaminants can also usefully be divided into organic and inorganic types. **Organic** compounds include all chemicals based on a skeleton of carbon atoms. Because carbon atoms easily combine to form chain, branched, and ring structures, there is a wide variety of organic compounds. Despite the variety, they have similarities that can be used in sampling, analysis, and removal. Chemists subclassify organic compounds based on families having similar structure and predictable properties. Organic gaseous contaminants include gases such as methane, but the majority are vapors.

All other gaseous contaminants are classified as **inorganic**. Most inorganic air contaminants of interest to ventilation engineers are gases (mercury is an important exception). Major chemical families of inorganic and organic gaseous contaminants, with examples of specific compounds, are shown in Table 5, along with information

Licensed for single user. © 2021 ASHRAE, Inc.

Table 5 Major Chemical Families of Gaseous Air Contaminants

No.	Family	Examples	Other Information
Inorganic Contaminants			
1.	Single-element atoms and molecules	Chlorine, radon, mercury	Chlorine is a strong respiratory irritant used as a disinfectant; outdoor sources include seawater, chlorinated pools, and road salt. Radon is an important soil gas. Mercury is the vapor in fluorescent light bulbs and tubes.
2.	Oxidants	Ozone, nitrogen dioxide, hydrogen peroxide	Corrosive; respiratory irritants.
3.	Reducing agents	Carbon monoxide	Toxic; fuel combustion product.
4.	Acid gases	Carbon dioxide, hydrogen chloride, hydrogen fluoride, hydrogen sulfide, nitric acid, sulfur dioxide, sulfuric acid	Carbon dioxide and hydrogen sulfide are only weakly acidic. Hydrogen sulfide is the main agent in sewer gas. Other members are corrosive and respiratory irritants. Some are important outdoor contaminants.
5.	Nitrogen compounds	Ammonia, hydrazine, nitrous oxide	Ammonia is used in cleaning products; it is a strong irritant. Hydrazine is used as an anticorrosion agent. Nitrous oxide (laughing gas) is used as an anesthetic.
6.	Miscellaneous	Arsine, phosphine	Used in the semiconductor industry.
Organic Contaminants			
7.	*n*-Alkanes	Methane, propane, *n*-butane, *n*-hexane, *n*-heptane, *n*-octane, *n*-nonane, *n*-decane, *n*-undecane, *n*-dodecane	*n*-Alkanes are linear molecules and relatively easily identified analytically. Along with the far more numerous branched alkanes, they are components of solvents such as mineral spirits.
8.	Branched alkanes	2-methyl pentane, 2-methyl hexane	Numerous; members are difficult to separate and identify. Many occur as components of products such as gasoline, kerosene, mineral spirits, etc.
9.	Alkenes and cyclic hydrocarbons	Ethylene, butadiene, 1-octene, cyclohexane, 4-phenyl cyclohexene (4-PC)	Ethylene gas is produced by ripening fruit (and used in the fruit industry). Some liquid members are components of gasoline, etc. 4-PC is responsible for "new carpet" odor.
10.	Chlorofluorocarbons	R-11 (trichlorofluoromethane), R-12 (dichlorodifluoromethane), R-114 (dichlorotetrafluoroethane)	Widely used as refrigerants; are being phased out because of their ozone-depleting potential.
11.	Chlorinated hydrocarbons	Carbon tetrachloride, chloroform, dichloromethane, 1,1,1-trichloroethane, trichloroethylene, tetrachloroethylene, *p*-dichlorobenzene	Dichlorobenzene, an aromatic chemical, is a solid used as an air freshener. Others shown here are liquids and effective nonpolar solvents. Some are used as degreasers or in the dry-cleaning industry.
12.	Halide compounds	Methyl bromide, methyl iodide	Low combustibility; some are used as flame retardants.
13.	Alcohols	Methanol, ethanol, 2-propanol (isopropanol), 3-methyl 1-butanol, ethylene glycol, 2-butoxyethanol, phenol, texanol	Strongly polar. Some (including 2-butoxyethanol and texanol) are used as solvents in water-based products. Phenol is used as a disinfectant. 3-methyl 1-butanol is emitted by some molds.
14.	Ethers	Ethyl ether, methyl tertiary butyl ether (MTBE), 2-butoxyethanol	Ethyl ether and 2-butoxyethanol are used as solvents. MTBE is added to gasoline to improve combustion in vehicle motors.
15.	Aldehydes	Formaldehyde, acetaldehyde, acrolein, benzaldehyde	Formaldehyde, acetaldehyde, and acrolein have unpleasant odors and are strong irritants formed during combustion of fuels and tobacco.
16.	Ketones	2-propanone (acetone), 2-butanone (MEK), methyl isobutyl ketone (MIBK), 2-hexanone	Medium-polarity chemicals; some are useful solvents. Acetone and 2-hexanone are emitted by some molds.
17.	Esters	Ethyl acetate, vinyl acetate, butyl acetate, texanol	Medium-polarity chemicals; some have pleasant odors and are added as fragrances to consumer products.
18.	Nitrogen compounds other than amines	Nitromethane, acetonitrile, acrylonitrile, urea, hydrogen cyanide, peroxyacetal nitrite (PAN)	Includes several different types of chemicals with few common properties. Acetonitrile is used as a solvent; urea is a metabolic product; PAN is found in vehicle exhaust.
19.	Aromatic hydrocarbons	Benzene, toluene, *p*-xylene, styrene, 1,2,4 trimethyl benzene, naphthalene, benz-α-pyrene	Benzene, toluene, and xylene are widely used as solvents and in manufacturing, and are ubiquitous in indoor air. Naphthalene is used as moth repellent.
20.	Terpenes	α-pinene, limonene	A variety of terpenes are emitted by wood. The two listed here have pleasant odors and are used as fragrances in cleaners, perfumes, etc.
21.	Heterocylics	Ethylene oxide, tetrahydrofuran, 3-methyl furan, 1,4-dioxane, pyridine, nicotine	Most are of medium polarity. Ethylene oxide is used as a disinfectant. Tetrahydrofuran and pyridine are used as solvents. Nicotine is a component of tobacco smoke.
22.	Organophosphates	Malathion, tabun, sarin, soman	Listed are components of agricultural pesticides and occur as outdoor air contaminants.
23.	Amines	Trimethylamine, ethanolamine, cyclohexylamine, morpholine	Typically have unpleasant odors detectable at very low concentrations. Some (cyclohexylamine and morpholine) are used as antioxidants in boilers.
24.	Monomers	Vinyl chloride, ethylene, methyl methacrylate, styrene	Potential to be released from their respective polymers (PVC, polythene, perspex, polystyrene) if materials are heated.
25.	Mercaptans and other sulfur compounds	Bis-2-chloroethyl sulfide (mustard gas), ethyl mercaptan, dimethyl disulfide	Sulfur-containing chemicals typically have unpleasant odors detectable at very low concentrations. Ethyl mercaptan is added to natural gas so that gas leaks can be detected by odor. Mustard gas has been used in chemical warfare.
26.	Organic acids	Formic acid, acetic acid, butyric acid	Formic and acetic acids (vinegar) are emitted by some types of wood. Butyric acid is a component of "new car" odor.
27.	Miscellaneous	Phosgene, siloxanes	Phosgene is a toxic gas released during combustion of some chlorinated organic chemicals. Siloxanes occur widely in consumer products, including adhesives, sealants, cleaners, and hair and skin care products.

Licensed for single user. © 2021 ASHRAE, Inc.

about occurrence and use. Some organics belong to more than one class and carry the attributes of both.

Another useful gaseous contaminant classification is polar versus nonpolar. There is a continuous distribution between these extremes. For **polar** compounds, charge separation occurs between atoms, which affects physical characteristics as well as chemical reactivity. Water is one of the best examples of a polar compound, and consequently polar gaseous contaminants tend to be soluble in water. **Nonpolar** compounds are much less soluble in water, but dissolve in nonpolar liquids. This classification provides the basis for dividing consumer products that contain organic compounds into water-based and solvent-based. Contaminant classes in Table 5 that are strongly polar include acid gases, chemicals containing oxygen (e.g., alcohols, aldehydes, ketones, esters, organic acids), and some nitrogen-containing chemicals. Nonpolar classes include all hydrocarbons (alkyl, alkene, cyclic, aromatic), chlorinated hydrocarbons, terpenes, and some sulfur-containing chemicals.

Because no single sampling and analysis method applies to every (or even most) potential contaminant, having some idea what the contaminants and their properties might be is very helpful. Contaminants have sources, and consideration of the locale, industries, raw materials, cleaners, and consumer products usually provides some guidance regarding probable contaminants. Material safety data sheets (MSDS) provide information on potentially harmful chemicals that a product contains, but the information is often incomplete. Once a potential contaminant has been identified, the *Merck Index* (Budavi 1996), the *Toxic Substances Control Act Chemical Substance Inventory* (EPA 1979), *Dangerous Properties of Industrial Materials* (Sax and Lewis 1988), and *Handbook of Environmental Data on Organic Chemicals* (Verschueren 1996) are all useful in identifying and gathering information on contaminant properties, including some known by trade names only. Chemical and physical properties can be found in reference books such as the *Handbook of Chemistry and Physics* (Lide 1996). Note that a single chemical compound, especially an organic one, may have several scientific names. To reduce confusion, the Chemical Abstracts Service (CAS) assigns each chemical a unique five- to nine-digit identifier number. Table 6 shows CAS numbers and some physical properties for selected gaseous contaminants. The volatility designation for organic chemicals (VVOC, VOC, SVOC) is explained in the section on Volatile Organic Compounds. Volatilities, expressed more exactly in boiling point and saturated vapor pressure data, are important in predicting airborne concentrations of gaseous contaminants in cases of spillage or leakage of liquids. For example, because of its much higher volatility, ammonia requires more rigorous safety precautions than ethylene glycol when used as a heat exchange fluid. In laboratories where several acids are stored, hydrochloric acid (hydrogen chloride) usually causes more corrosion than sulfuric or nitric acids because its greater gaseous concentration results in escape of more chemical. Additional chemical and physical properties for some of the chemicals in Tables 5 and 6 can be found in Chapter 33.

Harmful Effects of Gaseous Contaminants

Harmful effects may be divided into four categories: toxicity, irritation, odor, and material damage.

Toxicity. The harmful effects of gaseous pollutants on a person depend on both short-term peak concentrations and the time-integrated exposure received by the person. Toxic effects are generally considered to be proportional to the exposure dose, although individual response variation can obscure the relationship. The allowable concentration for short exposures is higher than that for long exposures. Safe exposure limits have been set for a number of common gaseous contaminants in industrial settings. This topic is covered in more detail in the section on Industrial Air Contaminants and in Chapter 10.

A few gaseous contaminants are also capable of causing cancer. Formaldehyde has recently been declared a known human carcinogen by the U.S. National Toxicology Program (NTP 2011), based on an earlier report issued by the International Agency for Research in Cancer (IARC 2004). The NTP also stated that styrene is "reasonably anticipated to be a human carcinogen" (NTP 2011).

Gaseous contaminants can also be responsible for chronic health effects when exposure to low levels occurs over a long period of time. Acetaldehyde, acrolein, benzene, 1,3-butadiene, 1,4-dichlorobenzene, formaldehyde, naphthalene, and nitrogen dioxide have recently been identified as priority chronic hazards in U.S. homes (Logue et al. 2011). More information on health effects of gaseous contaminants can be found in Chapter 10.

Irritation. Although gaseous pollutants may have no discernible continuing health effects, exposure may cause physical irritation to building occupants. This phenomenon has been studied principally in laboratories and nonindustrial work environments, and is discussed in more detail in the section on Nonindustrial Indoor Air Contaminants and in Chapter 10.

Odors. Gaseous contaminant problems often appear as complaints about odors, and these usually are the result of concentrations considerably below industrial exposure limits. Odors are discussed in more detail in Chapter 12. Note that controlling gaseous contaminants because they constitute a nuisance odor is fundamentally different from controlling a contaminant because it has a demonstrated health effect. Odor control frequently can use limited-capacity "peak-shaving" technology to drop peaks of odorous compounds below the odor threshold. Later reemission at a low rate is neither harmful nor noticed. Such an approach may not be acceptable for control of toxic materials.

Damage to Materials. Material damage from gaseous pollutants includes corrosion, embrittlement, and discoloration. Because these effects usually involve chemical reactions that need water, material damage from air pollutants is less severe in the relatively dry indoor environment than outdoors, even at similar gaseous contaminant concentrations. Contaminants that can corrode HVAC systems include seawater, acid gases (chlorine, hydrogen fluoride, hydrogen sulfide, nitrogen oxides and sulfur oxides), ammonia, and ozone. Corrosion from these gases can also cause electrical, electronic, and telephone switching systems to malfunction (ISA 1985).

Some dry materials can be significantly damaged. These effects are most serious in museums, because any loss of color or texture changes the essence of the object. Libraries and archives are also vulnerable, as are pipe organs and textiles. Consult Chapter 23 in the 2019 *ASHRAE Handbook—HVAC Applications* for additional information and an exhaustive reference list.

Units of Measurement

Concentrations of gaseous contaminants are usually expressed in the following units:

ppm = parts of contaminant by volume per million parts of air by volume

ppb = parts of contaminant by volume per billion parts of air by volume

1000 ppb = 1 ppm

mg/m^3 = milligrams of contaminant per cubic metre of air

$\mu g/m^3$ = micrograms of contaminant per cubic metre of air

Conversions between ppm and mg/m^3 are

$$ppm = [8.314(273.15 + t)/Mp]\ (mg/m^3) \quad (1)$$

$$mg/m^3 = [0.1203(Mp)/(273.15 + t)]\ (ppm) \quad (2)$$

where

M = relative molar mass of contaminant

[a]CAS = Chemical Abstracts Services.
[b]Volatility of organic chemicals complies with Table 9. VVOC adopted from the list produced by Salthammer (2016). Volatility of inorganic chemicals is gas if boiling point is less than 20°C, and vapor if boiling point is greater than 20°C.
[c]M = molar mass.
[d]Listed as a challenge gas for laboratory testing of gas-phase filter granular media using ASHRAE *Standard* 145.1.
[e]Listed as a challenge gas for testing full-size gas-phase filters using ASHRAE *Standard* 145.2.
[f]Commonly found in buildings and may impact indoor air quality (IAQ) (taken from list in Table 10).

p = mixture pressure, kPa
t = mixture temperature, °C

Concentration data are often reduced to standard temperature and pressure (i.e., 25°C and 101.325 kPa), in which case,

$$\text{ppm} = (24.46/M)\ (\text{mg/m}^3) \quad (3)$$

Using the 21°C standard temperature more familiar to engineers results in a conversion factor between ppm and mg/m^3 of 24.14 in Equation (3). A temperature of 0°C gives a corresponding conversion factor of 22.41. These calculations show that variations in indoor temperature are likely to impact conversion factors by 1% or less, and can probably be ignored. However, outdoor temperatures may result in conversion factors in Equations (1) and (2) that differ by 10% from indoor ones, so that indoor and outdoor data may need to be converted separately using the appropriate factors. The differences in the conversion factors are caused by the fact that gases contract and become denser as temperatures decrease. Concentrations expressed in ppm are temperature independent, because

Table 7 Gaseous Contaminant Sample Collection Techniques

Technique*	Advantages	Disadvantages
Active Methods		
1. Direct flow to detectors	Real-time readout, continuous monitoring possible Several pollutants possible with one sample (when coupled with chromatograph, spectroscope, or multiple detectors)	Average concentration must be determined by integration No preconcentration possible before detector; sensitivity may be inadequate On-site equipment often complicated, expensive, intrusive, and requires skilled operator
2. Capture by pumped flow through colorimetric detector tubes, papers, or tapes	Very simple, relatively inexpensive equipment and materials Immediate readout Integration over time	One pollutant per sample Relatively high detection limit Poor precision Requires multiple tubes, papers, or tapes for high concentrations or long-term measurements
3. Capture by pumped flow through solid adsorbent; subsequent desorption for concentration measurement	On-site sampling equipment relatively simple and inexpensive Preconcentration and integration over time inherent in method Several pollutants possible with one sample	Sampling media and desorption techniques are compound-specific Interaction between captured compounds and between compounds and sampling media; bias may result Gives only average over sampling period, no peaks Subsequent concentration measurement required
4. Collection in evacuated containers	Very simple on-site equipment No pump (silent) Several pollutants possible with one sample	Subsequent concentration measurement required Gives average over sampling period; no peaks Finite volume requires multiple containers for long-term or continuous measurement
5. Collection in nonrigid containers (specialized, commercially available sampling bags)	Simple, inexpensive on-site equipment (pumps required) Several pollutants possible with one sample	Cannot hold some pollutants Subsequent concentration measurement required Gives average over sampling period; no peaks Finite volume requires multiple containers for long-term or continuous measurement
6. Cryogenic condensation	Wide variety of organic pollutants can be captured Minimal problems with interferences and media interaction Several pollutants possible with one sample	Water vapor interference Subsequent concentration measurement required Gives average over sampling period; no peaks
7. Liquid impingers (bubblers)	Integration over time Several pollutants possible with one sample if appropriate liquid chosen	May be noisy Subsequent concentration measurement required Gives average over sampling period; no peaks
Passive Methods		
8. Passive colorimetric badges	Immediate readout possible Simple, unobtrusive, inexpensive No pumps, mobile; may be worn by occupants to determine average exposure	One pollutant per sample Relatively high detection limit Poor precision May require multiple badges for higher concentrations or long-term measurement
9. Passive diffusional samplers	Simple, unobtrusive, inexpensive No pumps, mobile; may be worn by occupants to determine average exposure	Subsequent concentration measurement required Gives average over sampling period; no peaks Poor precision

*All techniques except 1, 2, and 8 require laboratory work after completion of field sampling. Only first technique is adaptable to continuous monitoring and able to detect short-term excursions.

both the contaminant gas and the diluting air contract. However, concentrations expressed in mg/m^3 increase as temperature decreases, leading to lower ratios of ppm to mg/m^3.

Equations (1) to (3) are strictly true only for ideal gases, but generally are acceptable for dilute vaporous contaminants dispersed in ambient air.

Measurement of Gaseous Contaminants

The concentration of contaminants in air must be measured to determine whether indoor air quality conforms to occupational health standards (in industrial environments) and is acceptable (in nonindustrial environments).

Measurement methods for airborne chemicals that are important industrially have been published by several organizations, including NIOSH (1994) and OSHA (1995). Methods typically involve sampling air with pumps for several hours to capture contaminants on a filter or in an adsorbent tube, followed by laboratory analysis for detection and determination of contaminant concentration. Concentrations measured in this way can usefully be compared to 8 h industrial exposure limits.

Measurement of gaseous contaminants at the lower levels acceptable for indoor air is not always as straightforward. Relatively costly analytical equipment may be needed, and it must be calibrated and operated by experienced personnel.

Currently available sample collection techniques are listed in Table 7, with information about their advantages and disadvantages. Analytical measurement techniques are shown in Table 8, with information on the types of contaminants to which they apply. Tables 7 and 8 provide an overview of gaseous contaminant sampling and analysis, with the intent of allowing informed interaction with specialists.

Techniques 1, 2, and 8 in Table 7 combine sampling and analysis in one piece of equipment and give immediate, on-site results. The other sampling methods require laboratory analysis after the field work. Equipment using the first technique can be coupled with a

Table 8 Analytical Methods to Measure Gaseous Contaminant Concentration

Method	Description	Typical Application (Family)
Gas chromatography (using the following detectors)	Separation of gas mixtures by time of passage down absorption column	
Flame ionization	Change in flame electrical resistance caused by ions of pollutant	Volatile, nonpolar organics (7-27)
Flame photometry	Measures light produced when pollutant is ionized by a flame	Sulfur (25), phosphorous (22) compounds Most organics (7-27), except methane
Photoionization	Measures ion current for ions created by ultraviolet light	Halogenated organics (11, 12) Nitrogenated organics (18, 23)
Electron capture	Radioactively generated electrons attach to pollutant atoms; current measured	
Mass spectroscopy	Pollutant molecules are charged, passed through electrostatic magnetic fields in vacuum; path curvature depends on mass of molecule, allowing separation and counting of each type	Volatile organics (7-27 with boiling point <65°C)
Infrared spectroscopy, including Fourier transform IR (FTIR) and photoacoustic IR	Absorption of infrared light by pollutant gas in a transmission cell; a range of wavelengths is used, allowing identification and measurement of individual pollutants	Acid gases (4, 26), carbon monoxide (3) Many organics; any gas with an absorption band in the infrared (7-27)
High-performance liquid chromatography (HPLC)	Pollutant is captured in a liquid, which is then passed through a liquid chromatograph (analogous to a gas chromatograph)	Aldehydes (15), ketones (16) Phosgene (27) Nitrosamines (18, 23) Cresol, phenol (13)
Colorimetry	Chemical reaction with pollutant in solution yields a colored product whose light absorption is measured	Ozone (2) Oxides of nitrogen (2) Formaldehyde (15)
Fluorescence and pulsed fluorescence	Pollutant atoms are stimulated by a monochromatic light beam, often ultraviolet; they emit light at characteristic fluorescent wavelengths, whose intensity is measured	Sulfur dioxide (4) Carbon monoxide (3)
Chemiluminescence	Reaction (usually with a specific injected gas) results in photon emission proportional to concentration	Ozone (2) Nitrogen compounds (5, 18, 23) Some organics (7-27)
Electrochemical	Pollutant is bubbled through reagent/water solution, changing its conductivity or generating a voltage	Ozone (2) Hydrogen sulfide (4) Acid gases (4, 26)
Titration	Pollutant is absorbed into water and known quantities of acid or base are added to achieve neutrality	Acid gases (4, 26) Basic gases (5, 23)
Ultraviolet absorption	Absorption of UV light by a cell through which the polluted air passes is measured	Ozone (2) Aromatics (19) Sulfur dioxide (4) Oxides of nitrogen (2) Carbon monoxide (3)
Atomic absorption	Contaminant is burned in a hydrogen flame; a light beam with a spectral line specific to the pollutant is passed through the flame; optical absorption of the beam is measured	Mercury vapor (1)
Surface acoustic wave, flexural plate wave, etc.	Contaminant adsorption on a substrate alters the resonant vibration frequency or vibration transmittance characteristics	
Chemiresistor (metal oxide)	Contaminant interacts with coated metal oxide surface at high temperature, changing the resistance to electrical current	Carbon monoxide (3), hydrogen sulfide (4), organic vapors (7-27)

Sources: ATC (1990), Lodge (1988), NIOSH (1977, 1994), and Taylor et al. (1977).

data logger to perform continuous monitoring and to obtain average concentrations over a time period. Most of the sample collection techniques can capture several contaminants. Several allow pollutants to accumulate or concentrate over time so that very low concentrations can be measured.

Some analytical measurement techniques are specific for a single pollutant, whereas others can provide concentrations for many contaminants simultaneously. Note that formaldehyde requires different measurement methods from other volatile organic compounds.

Measurement instruments used in industrial situations should be able to detect contaminants of interest at about one-tenth of **threshold limit value (TLV)** levels, published annually by ACGIH. If odors are of concern, detection sensitivity must be at odor threshold levels. Procedures for evaluating odor levels are given in Chapter 12.

Note that information in Tables 7 and 8 is not sufficient in itself to allow preparation of a measurement protocol. ASHRAE's proposed *Guideline* 27P provides guidance on developing a test protocol, including criteria for deciding whether to use instantaneous measurement or integrated sampling techniques, selection of locations to test, and information to obtain about the test building (building and air-handling system layout, space occupancy and use patterns, environmental conditions and HVAC operating parameters during the test period, etc.). The guideline also presents practical information on test equipment use.

3.1 VOLATILE ORGANIC COMPOUNDS

The entire range of organic indoor pollutants has been categorized by volatility, as indicated in Table 9 (WHO 1989). No sharp limits

Licensed for single user. © 2021 ASHRAE, Inc.

Table 9 Classification of Indoor Organic Contaminants by Volatility

Description	Abbreviation	Boiling Point Range, °C
Very volatile (gaseous) organic compounds	VVOC	0 to 50–100
Volatile organic compounds	VOC	50–100 to 240–260
Semivolatile organics (pesticides, polynuclear aromatic compounds, plasticizers)	SVOC	240–260 to 380–400

Source: WHO (1989).
Notes:
Polar compounds and VOCs with higher mol masses appear at higher end of each boiling-point range.
The EPA uses a different definition of VOC for regulatory purposes.

exist between the categories, which are defined by boiling-point ranges. Volatile organic compounds (VOCs) have attracted considerable attention in nonindustrial environments. They have boiling points in the range of approximately 50 to 250°C and vapor pressures greater than about 0.1 to 0.01 Pa. [Note that the EPA has a specific regulatory definition of VOCs (*Code of Federal Regulations* 40CFR51.100) that must be consulted if regulated U.S. air emissions are the matter of interest. Although similar to the definition here, it is more complex, with some excluded compounds and specified test methods.]

Sources of VOCs include solvents, reagents, and degreasers in industrial environments; and furniture, furnishings, wall and floor finishes, cleaning and maintenance products, and office and hobby activities in nonindustrial environments. Which gas contaminants are likely in an industrial environment can usually best be identified from the nature of the industrial processes, and that is the recommended first step. This discussion focuses on indoor VOCs because they are usually more difficult to identify and quantify.

Berglund et al. (1988) found that the sources of VOCs in nonindustrial indoor environments are confounded by the variable nature of emissions from potential sources. Emissions of VOCs from indoor sources can be classified by their presence and rate patterns. For example, emissions are continuous and regular from building materials and furnishings (e.g., carpet and composite-wood furniture), whereas emissions from other sources can be continuous but irregular (e.g., paints used in renovation work), intermittent and regular (e.g., VOCs in combustion products from gas stoves or cleaning products), or intermittent and irregular (e.g., VOCs from carpet shampoos) (Morey and Singh 1991).

Many "wet" emission sources (paints and adhesives) have very high emission rates immediately after application, but rates drop steeply with time until the product has cured or dried. New "dry" materials (carpets, wall coverings, and furnishings) also emit chemicals at higher rates until aged. Decay of these elevated VOC concentrations to normal constant-source levels can take weeks to months, depending on emission rates, surface areas of materials, and ventilation protocols. Renovation can cause similar increases of somewhat lower magnitude. The total VOC concentration in new office buildings at the time of initial occupancy can be 50 to 100 times that present in outdoor air (Sheldon et al. 1988a, 1988b). In new office buildings with adequate outdoor air ventilation, these ratios often fall to less than 5:1 after 4 or 5 months of aging. In older buildings with continuous, regular, and irregular emission sources, indoor/outdoor ratios of total VOCs may vary from nearly 1:1, when maximum amounts of outdoor air are being used in HVAC systems, to greater than 10:1 during winter and summer months, when minimum amounts of outdoor air are being used (Morey and Jenkins 1989; Morey and Singh 1991).

Although direct VOC emissions are usually the primary source of VOCs in a space, some materials act as sinks for emissions and then become secondary sources as they reemit adsorbed chemicals (Berglund et al. 1988). Adsorption may lower the peak concentrations achieved, but the subsequent desorption prolongs the presence of indoor air pollutants. Sink materials include carpet, fabric partitions, and other fleecy materials, as well as ceiling tiles and wallboard. The type of material and compound affects the rate of adsorption and desorption (Colombo et al. 1991). Experiments conducted in an IAQ test house confirmed the importance of sinks when trying to control the level of indoor VOCs (Tichenor et al. 1991). Longer periods of increased ventilation lessen sink and reemission effects. Early models used empirically derived adsorption and desorption rates to predict the behavior of sinks. A better modeling approach uses intrinsic characteristics of the adsorbed contaminant and the sink material (Little and Hodgson 1996). ASHRAE research project RP-1321 refined and extended this approach to enable prediction of IAQ in spaces containing sink materials (Yang et al. 2010).

VanOsdell (1994) reviewed research studies of indoor VOCs as part of ASHRAE research project RP-674, and found more than 300 compounds had been identified indoors and that there was no agreement on a short list of key VOCs. The large number of VOCs usually found indoors, and the impossibility of identifying all of them in samples, led to the concept of **total VOC (TVOC)**. Some researchers have used TVOC to represent the sum of all detected VOCs. TVOC concentrations are often reported as everything detected in the air by analysis methods such as photoionization detectors (PID) or flame ionization detectors (FID). Therefore, all methods for TVOC determination are intrinsically of low to moderate accuracy because of variations in detector response to different classes of VOCs. Despite the limitations, TVOC can be useful, and is widely used for mixed-contaminant atmospheres. Both theoretical and practical limitations of the TVOC approach have been discussed (Hodgson 1995; Otson and Fellin 1993). Wallace et al. (1991) showed that individual VOC concentrations in homes and buildings are two to five times those of outdoors, and personal TVOC exposures resulting from normal daily activities were estimated to be two to three times greater than general indoor air concentrations.

Personal activities frequently bring individuals close to air contaminant sources. In addition, exposure from contaminated air jets depends on the complex airflows around the body, including the main flow stream, air turbulence, and obstructions nearby (Rodes et al. 1991). Individual organic compounds seldom exceed 0.05 mg/m^3 (50 μg/m^3) in indoor air. An upper extreme average concentration of TVOCs in normally occupied houses is approximately 20 mg/m^3.

The EPA's Large Buildings Study (Brightman et al. 1996) developed the VOC sample target list shown in Table 10 to identify common VOCs that should be measured. Lists of common indoor VOCs prepared by other organizations are similar.

Because chlorofluorocarbons (CFCs) are hydrocarbons with some hydrogen atoms replaced by chlorine and fluorine atoms, they are classed as organic chemicals. They have been widely used as heat transfer gases in refrigeration applications, blowing agents, and propellants in aerosol products (including medications and consumer products) and as expanders in plastic foams. Exposure to CFCs and HCFCs occurs mainly through inhalation, and can occur from leaks in refrigeration equipment or during HVAC maintenance.

Volatile organic compounds produced by microorganisms as they grow are referred to as **microbial VOCs (MVOCs)**. Of particular interest are those emitted by fungi contaminating water-damaged buildings. Usually, mixtures of MVOCs that are common to many different species (as well as to industrial chemicals) are produced. However, there are also compounds specific to a particular genus or species. Analysis for MVOCs is generally by gas chromatography/mass spectrometry (GC/MS) with thermal desorption.MVOCs include a variety of chemical classes including alcohols, ketones, organic acids, and heterocyclic compounds, among others. Many

*Properties of these VOCs can be found in Table 6.

have extremely low odor thresholds. Examples in Table 5 include acetone, ethanol, 3-methyl 1-butanol, 2-hexanone, and 3-methyl furan. More information on MVOCs can be found in Horner and Miller (2003).

It is not known whether exposure to MVOCs is likely to cause adverse health effects on its own, because MVOCs are not likely to comprise the sole exposure. However, many are quite objectionable and may be irritating. At the very least, they may indicate a potential mold growth problem in a building, and often cause complaints about air quality. Note that MVOCs are distinct from fungal mycotoxins, which are nonvolatile and therefore not odorous.

Controlling Exposure to VOCs

Much can be done to reduce building occupants' exposures to emissions of VOCs from building materials and products and to prevent outdoor VOCs from being brought into buildings. In most cases, the economically and technically preferred hierarchy for indoor contaminant reduction is (1) source control, (2) dilution with ventilation air, and (3) air filtration (local exhaust is seldom used in commercial buildings, though it is common in industrial facilities). Chapter 46 of the 2019 *ASHRAE Handbook—HVAC Applications* provides a full discussion.

3.2 SEMIVOLATILE ORGANIC COMPOUNDS

Semivolatile organic compounds (SVOCs) are organic chemicals with boiling points ranging from approximately 240 to 400°C and vapor pressures of 10^{-12} to 10^{-2} kPa. Low vapor pressures mean that SVOCs are present in the air in lower concentrations than VOCs, and tend to outgas more slowly and condense more readily, sticking to floors, furniture, and clothing and remaining in the surroundings for longer periods of time. Indoor SVOCs are of special interest today because of growing concerns about their effects on health.

The SVOC group includes a number of familiar chemical types, including

- Polychlorinated biphenyls (PCBs), once in common use as flame retardants but now largely banned
- Polycyclic aromatic hydrocarbons (PAHs), originating from indoor and outdoor combustion sources and traffic emissions
- Phthalates, widely used as plasticizers to improve flexibility and durability of plastics in consumer products and food packaging
- Chlorine- and phosphate-containing organic pesticides
- Organic phosphates, chlorine-containing compounds, and polybrominated diphenyl ethers (PBDEs) used as flame retardants

Many SVOCs are more common indoors than outdoors. They can be the active ingredients in cleaning products and personal care products, and major additives in materials such as floor coverings, furnishings, electronic components, foams, and food containers. They also occur in antimicrobials, sealants (e.g., silicones), heat transfer agents, and pesticides (Weschler and Nazaroff 2008). More than a thousand high-production-volume organic chemicals are produced or imported into the United States in amounts greater than 450,000 kg per year (EPA 2007), including a number of SVOCs. SVOCs may persist in the indoor environment for years after introduction. Exposures can occur via inhalation, ingestion, and dermal pathways through both gaseous and adsorption onto suspended particulate matter and floor dust (Weschler and Nazaroff 2010).

Selected SVOCs, such as PAHs, have long histories of known health effects. However, more recently, effects on the indoor environment from use of SVOCs in commercial products are becoming more widely understood. SVOC health impacts generally are chronic, with increasing and cumulative body burdens. Potential health consequences include endocrine disruption (Adibi et al. 2003; Apelberg et al. 2007), cancer (Bostrom et al. 2002), allergy (Bornehag et al. 2004), and neurodevelopment and behavioral problems (e.g., autism, attention deficit disorder) (Howdeshell 2002; Jacobson and Jacobson 1996).

Indoor concentrations depend on the SVOC and the source, but in general range between 0.002 and 5000 ng/m^3 (Weschler and Nazaroff 2008). In one study, a major source of brominated flame retardants in office buildings was found to be computer servers (Batterman et al. 2010), with the median concentration in settled dust being 8754 ng/g. One distribution route was through the HVAC system. SVOCs are not easily detected, and few can be measured by common sampling and analytical methods for indoor environmental monitoring. Improved standard measurement methodologies are currently being developed to help understand the extent of the prevalence of SVOCs in the indoor environment and the associated health risks from exposure.

3.3 INORGANIC GASES

Several inorganic gases are of concern because of their effects on human health and comfort and on materials. These include carbon dioxide, carbon monoxide, oxides of nitrogen, sulfur dioxide, ozone, and ammonia. Most have both outdoor and indoor sources.

Carbon dioxide (CO_2) or **carbonic acid** gas is produced by human respiration. It is not normally considered to be a toxic air contaminant, but it can be a simple asphyxiant (by oxygen displacement) in confined spaces such as submarines. CO_2 is found in the ambient environment at 330 to 370 ppm. Levels in the urban environment may be higher because of emissions from gasoline and, more often, diesel engines. Measurement of CO_2 in occupied spaces has been widely used to evaluate the amount of outdoor air supplied to indoor spaces. In ASHRAE *Standard* 62.1, a level of 1000 to 1200 ppm (or 700 ppm above outdoor air) has been suggested as being representative of delivery rates of 7.5 L/s per person of outdoor air when CO_2 is measured at equilibrium concentrations and at occupant densities of 10 people per 100 m^2 of floor space. Measuring CO_2 level before it has reached steady-state conditions can lead to inaccurate conclusions about the amount of outdoor air used in the building.

Carbon monoxide (CO) is an odorless, colorless, and tasteless gas produced by incomplete combustion of hydrocarbons. It is a common ambient air pollutant and is very toxic. Common indoor sources of CO include gas stoves, kerosene lanterns and heaters, mainstream and sidestream tobacco smoke, woodstoves, and unvented or improperly vented combustion sources. Building makeup

Licensed for single user. © 2021 ASHRAE, Inc.

air intakes located at street level or near parking garages can entrain CO from automobiles and carry it to the indoor environment. Air containing carbon monoxide may also enter the building directly if the indoor space is at negative pressure relative to outdoors. Major predictors of indoor CO concentrations are indoor fossil fuel sources, such as gas furnaces, hot water heaters, and other combustion appliances; attached garages; and weather inversions. Carbon monoxide can be a problem in indoor ice skating arenas where gasoline- or propane-powered resurfacing machines are used. Levels in homes only rarely exceed 5 ppm. In one sample of randomly selected homes, 10% failed a backdrafting test (Conibear et al. 1996). Under backdrafting conditions, indoor CO sources may contribute to much higher, dangerous levels of CO.

Oxides of nitrogen (NO_x) indoors result mainly from cooking appliances, pilot lights, and unvented heaters. Sources generating CO often produce nitric oxide (NO) and nitrogen dioxide (NO_2), as well. Underground or attached parking garages can also contribute to indoor concentrations of NO_x. An unvented gas cookstove contributes approximately 0.025 ppm of nitrogen dioxide to a home. During cooking, 0.2 to 0.4 ppm peak levels may be reached (Samet et al. 1987). Ambient air pollution from vehicle exhausts in urban locations can contribute NO_x to the indoor environment in makeup air. Oxides of nitrogen also are present in mainstream and sidestream tobacco smoke; NO and NO_2 are of most concern.

Sulfur dioxide (SO_2) can result from emissions of kerosene space heaters; combustion of fossil fuels such as coal, heating oil, and gasoline; or burning any material containing sulfur. Thus, sulfur dioxide is a common ambient air pollutant in many urban areas.

Ozone (O_3) is an oxidant that forms outdoors at ground level when hydrocarbons (usually from fossil fuels) and oxides of nitrogen react with ultraviolet radiation in sunlight to produce photochemical smog.

Indoor ozone mainly comes from outdoor air through infiltration or mechanical ventilation, which makes the indoor ozone concentration change in a similar pattern to that of outdoor ozone, both daily and seasonally. Indoor ozone concentrations from this source are typically about 20 to 30% of outdoor values for moderate-ventilation rooms and about 50 to 70% of outdoor values for highly ventilated rooms (Weschler et al. 1989). In addition, indoor devices such as electronic air cleaners (Boelter and Davidson 1997), photocopiers, and laser printers (Allen et al. 1978; Valuntaite and Girgzdiene 2007; Worthan and Black 1999) are important indoor ozone sources. Ozone can also form when ozone-generating devices marketed as portable air cleaners and ionizers are used in the indoor environment (Esswein and Boeniger 1994), though use of such devices is now banned in some jurisdictions.

Indoor ozone can react with many indoor VOCs (especially those with unsaturated carbon/carbon bonds), surfaces of furniture, and other building materials such as carpet and HVAC ventilation duct. These can all serve as indoor ozone sinks, but almost all ozone-initiated indoor chemical reactions lead to secondary pollution. Ozone can react with many indoor terpenes to form aerosol particles (Vartiainen et al. 2006; Weschler and Shields 1999); presence of ozone and d-limonene can lead to many hydroperoxides, such as hydrogen peroxide (H_2O_2) (Li et al. 2002). Field and laboratory experiments show that reaction of ozone with indoor surfaces, household products, and building materials generates aldehydes and submicron particles (Aokia and Tanabe 2007; Destaillats et al. 2006; Wang and Morrison 2006). Interaction between ozone and carpet can also generate other aldehydes (Morrison and Nazaroff 2002). Exposure of ventilation ducts (including liner, duct sealing caulk, and neoprene) to ozone could increase emission of aldehydes (Morrison et al. 1998). A number of the secondary contaminants are toxic or act as respiratory irritants.

Ammonia (NH_3) is a colorless gas with a sharp and intensely irritating odor. It is lighter than air and readily soluble in water. Ammonia is itself a refrigerant and fertilizer and is also a high-volume industrial chemical used in the manufacture of a wide variety of products (e.g., nitrogen fertilizers, nitric acid, synthetic fibers, explosives, and many others). In nature, ammonia is an animal metabolism by-product formed by decomposition of uric acid. As an indoor air contaminant, ammonia generally originates in synthetic cleaners and as a metabolic by-product.

Mercury is a naturally occurring element found in air, water, and soil. It exists in several forms: elemental or metallic mercury (a shiny, silver-white metal liquid at room temperature and a colorless, odorless gas if heated), inorganic mercury compounds, and organic mercury compounds.

Mercury is classified as a hazardous air pollutant under the Clean Air Act. Exposures to mercury can affect the human nervous system and harm the brain, heart, kidneys, lungs, and immune system.

One concern is breathing mercury vapor, which can occur when elemental mercury or products containing elemental mercury release mercury to the air, particularly in warm or poorly ventilated indoor spaces. Typically, mercury is released into the atmosphere in one of three forms: elemental mercury, which can remain in the atmosphere for up to a year and travel globally before being transformed; particle-bound mercury; or oxidized mercury [sometimes called ionic or reactive gaseous mercury (RGM)].

Exposure is most likely to occur during mining, production, and transportation of mercury, as well as mining and refining of gold and silver ores. Coal-burning power plants are the largest human-caused source of mercury emissions to the air in the United States, accounting for over 50% of all domestic human-caused mercury emissions (EPA 2017). Mercury is commonly found in thermometers, manometers, barometers, gages, valves, switches, batteries, and high-intensity discharge (HID) lamps. It is also used in dental amalgams, preservatives, heat transfer technology, pigments, catalysts, and lubricating oils.

The U.S. Occupational Health and Safety Administration (OSHA) set a mercury permissible exposure limit (PEL) of 0.1 mg/m^3 (8 h time-weighted average [TWA]). Some state OSHA programs regulate a stricter mercury vapor limit of 0.05 mg/m^3 (8 h TWA). Additionally, the American Conference of Governmental Industrial Hygienists (ACGIH) recommends a guideline of 0.025 mg/m^3.

Mercury hazards are addressed in specific standards for the general industry, shipyard employment, and the construction industry.

Controlling Exposures to Inorganic Gases

As for VOCs, the three main methods of control for inorganic gaseous contaminants are (1) source control, (2) ventilation control, and (3) removal by filters. Chapter 46 of the 2019 *ASHRAE Handbook—HVAC Applications* provides more detail on these methods.

4. AIR CONTAMINANTS BY SOURCE

Some air contaminants are commonly encountered and addressed as groups or single components originating from a source or having other common characteristics. Outdoor air contaminants, though widely varied between locations, are regulated uniformly across the United States and can usefully be considered as a separate category worthy of common consideration. Radioactive air contaminants also vary widely, but they too have many commonalities. This section addresses the commonalities and characteristics of air contaminants as a function of source or their common characteristics.

4.1 OUTDOOR AIR CONTAMINANTS

The total amount of suspended particulate matter in the atmosphere can influence the loading rate of air filters and their selection. The amount of soot that falls in U.S. cities ranges from 7 to 70 Mg/km^2 per month. Soot fall data indicate effectiveness of smoke

abatement and proper combustion methods, and serve as comparative indices of such control programs. However, the data are of limited value to the ventilating and air-conditioning engineer, because they do not accurately represent airborne soot concentrations.

Concentrations of outdoor pollutants are important, because they may determine indoor concentrations in the absence of indoor sources. Table 11 presents typical urban outdoor concentrations of some common gaseous pollutants. Higher levels might be found if the building under consideration were located near a major source of contamination, such as a power plant, a refinery, freeway, or a sewage treatment plant. Note that levels of sulfur dioxide and nitrogen dioxide, which are often attached to particles, may be reduced by about half by building filtration systems. Also, ozone is a reactive gas that can be significantly reduced by contact with ventilation system components (e.g., ductwork or other metal surfaces) (Weschler et al. 1989).

The U.S. Environmental Protection Agency identifies several important outdoor contaminants as criteria pollutants. The list includes carbon monoxide, nitrogen dioxide, ozone, sulfur dioxide, suspended particulate matter in two size ranges, and lead (Pb) particulate matter. Standards set for these contaminants are of two types: primary, which are intended to provide health protection; and secondary, which provide welfare and environmental protection. Current standards are shown in Table 12. Levels of these contaminants are measured at a large number of locations in the United States and published by the EPA each year (*Code of Federal Regulations* 40CFR50).

Daily concentrations of VOCs in outdoor air can vary drastically (Ekberg 1994). These variations derive from vehicle traffic density, wind direction, industrial emissions, and photochemical reactions.

4.2 INDUSTRIAL AIR CONTAMINANTS

Many industrial processes produce significant quantities of air contaminants in the form of dusts, fumes, smokes, mists, vapors, and gases. Particulate and gaseous contaminants are best controlled at the source, so that they are neither dispersed through the factory nor allowed to increase to toxic concentration levels. Dilution ventilation is much less effective than local exhaust for reducing contamination from point-source emissions, and is used for control only when sources are distributed and not amenable to capture by an exhaust hood. For sources generating high levels of contaminants, it may also be necessary to provide equipment that reduces the amount of material discharged to the atmosphere (e.g., a dust collector for particulate contaminants and/or a high-dwell-time gas-phase media bed for gaseous contaminants). Control methods are covered in Chapters 29 and 30 of the 2020 *ASHRAE Handbook—*

Licensed for single user. © 2021 ASHRAE, Inc.

HVAC Systems and Equipment and Chapters 32 and 46 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Reducing concentrations of all contaminants to zero is not economically feasible. Absolute control of all contaminants cannot be maintained, and workers can assimilate small quantities of various toxic materials without injury. The science of industrial hygiene is based on the facts that most air contaminants become toxic only if their concentration exceeds a maximum allowable limit for a specified period, and that workers can "detoxify" by being away from the workplace for a period of time. Allowable limits for work environments are covered in Chapter 10. Some commercial workspaces must also comply with OSHA.

Although the immediately dangerous to life and health (IDLH) toxicity limit is rarely a factor in HVAC design, HVAC engineers should consider it when deciding how much recirculation is needed in a given system. Ventilation airflow must never be so low that the concentration of any gaseous contaminant could rise to the IDLH level. Another toxic effect that may influence design is loss of sensory acuity because of gaseous contaminant exposure. For example, high concentrations of hydrogen sulfide, which has a very unpleasant odor, effectively eliminate a person's ability to smell the gas. Carbon monoxide, which has no odor to alert people to its presence, affects psychomotor responses and could be a problem in working environments such as air traffic control towers and vehicle repair shops. Clearly, waste anesthetic gases should not be allowed to reach levels in operating suites such that the alertness of any of the personnel is affected. NIOSH recommendations are frequently based on such subtle effects.

4.3 COMMERCIAL, INSTITUTIONAL, AND RESIDENTIAL INDOOR AIR CONTAMINANTS

Indoor air quality in residences, offices, and other indoor, nonindustrial environments is a widespread concern (NRC 1981; Spengler et al. 1982). Exposure to indoor pollutants can be as important as exposure to outdoor pollutants because a large portion of the population spends up to 90% of their time indoors and because indoor pollutant concentrations are frequently higher than corresponding outdoor contaminant levels.

For facilities such as hospitals and clinics, where occupants may have more vulnerable immune systems, it is essential to remove air contaminants, especially viable organisms, to prevent any possibility of respiratory issues. Therefore, it is important to understand the specific health care facility and its patient population when designing the HVAC system.

In schools and research institutes, good indoor air quality is key for teachers, staff, and students for peak productivity and the greatest opportunity for success. EPA (2016b) provides IAQ guidance for these applications.

Indoor air quality is also important in museums and galleries. Particulate contaminants in air can permanently damage valuable collectibles through abrasion or soiling, and gaseous pollutants may cause damage through chemical attacks; see Chapter 23 of the 2019 *ASHRAE Handbook—HVAC Applications* for details.

Symptoms of exposure to indoor pollutants include coughing; sneezing; eye, throat, and skin irritation; nausea; breathlessness; drowsiness; headaches; and depression. Rask (1988) suggests that when 20% of a single building's occupants suffer such irritations, the structure is suffering from **deficient indoor air quality (DIAQ)**, previously referred to as **sick building syndrome (SBS)**. Case studies of such occurrences have consisted of analyses of questionnaires submitted to building occupants, measurements of contaminant levels, or both. Some attempts to relate irritations to gaseous contaminant concentrations are reported (Berglund et al. 1986; Cain et al. 1986; Lamm 1986; Mølhave et al. 1982). The correlation of reported complaints with gaseous pollutant concentrations is not strong; many factors affect these less serious responses to pollution. In general, physical irritation does not occur at odor threshold concentrations.

Symptoms of exposure include coughing; sneezing; eye, throat, and skin irritation; nausea; breathlessness; drowsiness; headaches; and depression. Rask (1988) suggests that when 20% of a single building's occupants suffer such irritations, the structure is suffering from **sick building syndrome (SBS)**. Case studies of such occurrences have consisted of analyses of questionnaires submitted to building occupants, measurements of contaminant levels, or both. Some attempts to relate irritations to gaseous contaminant concentrations are reported (Berglund et al. 1986; Cain et al. 1986; Lamm 1986; Mølhave et al. 1982). The correlation of reported complaints with gaseous pollutant concentrations is not strong; many factors affect these less serious responses to pollution. In general, physical irritation does not occur at odor threshold concentrations.

Characterization of indoor air quality has been the subject of numerous recent studies. ASHRAE *Indoor Air Quality (IAQ) Conference Proceedings* discuss indoor air quality problems and some practical controls. ASHRAE *Standard* 62.1 addresses many indoor air quality concerns. Table 13 shows sources, source locations, and typical indoor and outdoor concentration ranges of several key contaminants found in indoor environments. Chapter 10 has further information on indoor health issues.

Knowledge of sources frequently present in different types of buildings can be useful when investigating the causes of DIAQ. Common nonindustrial indoor sources are discussed in some detail here. Technical advances allow generation rates to be measured for several of these sources. These rates are necessary inputs for design of filter control equipment; full details are given in Chapter 46 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Building materials and **furnishing** sources have been well studied. Particleboard, which is usually made from wood chips bonded with a phenol-formaldehyde or other resin, is widely used in current construction, especially for mobile homes, carpet underlay, and case goods. These materials, along with ceiling tiles, carpeting, wall coverings, office partitions, adhesives, and paint finishes, emit formaldehyde and other VOCs. Latex also contains mercury and emits mercury vapor. Although emission rates for these materials decline steadily with age, the half-life of emissions is surprisingly long. Black and Bayer (1986), Mølhave et al. (1982), and Nelms et al. (1986) report on these sources.

Ventilation systems may be a source of VOCs (Mølhave and Thorsen 1990). The interior of the HVAC system can have large areas of porous material used as acoustical liner that can adsorb odorous compounds, or these compounds can deposit on HVAC system surfaces. These materials can also hold nutrients and, with moisture, can become a reservoir for microorganisms. Microbial contaminants produce characteristic VOCs [microbial VOCs (MVOCs)] associated with their metabolism. Other HVAC components, such as condensate drain pans, fouled cooling coils, and some filter media, may support microbiological life. Deodorants, sealants, and encapsulants are also sources of VOCs in HVAC systems.

Equipment sources in commercial and residential spaces have generation rates that are usually substantially lower than in the industrial environment. Because these sources are rarely hooded, emissions go directly to the occupants. In commercial spaces, the chief sources of gaseous contaminants are office equipment, including dry-process copiers (ozone); liquid-process copiers (VOCs); diazo printers (ammonia and related compounds); carbonless copy paper (formaldehyde); correction fluids, inks, and adhesives (various VOCs); and spray cans, cosmetics, and so forth (Miksch et al. 1982). Three-dimensional (3D) printers can also be a source of particles and vapors (Azimi et al. 2016; Davis et al. 2016). Medical and dental activities generate pollutants from the escape of anesthetic gases

Table 13 Sources and Indoor and Outdoor Concentrations of Selected Indoor Contaminants

Contaminant	Sources of Indoor Contaminants	Typical Indoor Concentration	Typical Outdoor Concentration	Locations
Carbon monoxide	Combustion equipment, engines, faulty heating systems	0.5 to 5 ppm[a] (without gas stoves) 5 to 15 ppm[a] (with gas stoves)	2 ppm[a]	Indoor ice rinks, homes, cars, vehicle repair shops, parking garages
$PM_{2.5}$	Stoves, fireplaces, cigarettes, condensation of volatiles, aerosol sprays, cooking	7 to 10 μg/m^3[a]	<10 μg/m^3[a]	Homes, offices, cars, public facilities, bars, restaurants
PM_{10}	Combustion, heating system, cooking	40 to 60 μg/m^3[a]	60 μg/m^3[a]	Homes, offices, transportation, restaurants
Organic vapors	Combustion, solvents, resin products, pesticides, aerosol sprays, cleaning products, building materials, paints	Different for each VOC[c] (2 to 5 times outdoor levels)	See Table 11	Homes, restaurants, public facilities, offices, hospitals
Nitrogen dioxide	Combustion, gas stoves, water heaters, gas-fired dryers, cigarettes, engines	<8 ppb[a] (without combustion appliances)		
		>15 ppb with combustion appliances)	15 ppb[a]	Homes, indoor ice rinks
Nitric oxide	Combustion, gas stoves, water heaters, gas-fired dryers, cigarettes, engines		Various	Homes, any building with combustion source
Sulfur dioxide	Heating system	20 μg/m^3[b]	<20 μg/m^3[b] 3 ppb[a]	Mechanical/furnace rooms
Formaldehyde	Insulation, product binders, pressed wood products, carpets	0.1 to 0.3 ppm[a]	NA	Homes, schools, offices
Radon and progeny	Building materials, groundwater, soil	1.3 pCi/L[a]	4 pCi/L[a]	Homes, schools
Carbon dioxide	Combustion appliances, humans, pets	600 to 1000 ppm[c]	300 to 500 ppm[c]	Indoors and outdoors
Biological contaminants	Humans, pets, rodents, insects, plants, fungi, humidifiers, air conditioners	NA	NA (lower than indoor levels)	Homes, hospitals, schools, offices, public facilities
Ozone	Electric arcing, electronic air cleaners, copiers, printers	42 ppb[d]	70 ppb[a]	Airplanes, offices, homes

(nitrous oxide and isoflurane) and from sterilizers (ethylene oxide). The potential for asphyxiation is always a concern when compressed gases are present, even if that gas is nitrogen. In residences, the main sources of equipment-derived pollutants are gas ranges, wood stoves, printers, and kerosene heaters. Venting is helpful, but some pollutants escape into the occupied area. The pollutant contribution by gas ranges is somewhat mitigated by the fact that they operate for shorter periods than heaters. The same is true of showers, which can contribute to radon and halocarbon concentrations indoors.

Cleaning agents and **other consumer products** can act as contaminant sources. Commonly used liquid detergents, waxes, polishes, spot removers, and cosmetics contain organic solvents that volatilize slowly or quickly. Mothballs and other pest control agents emit organic vapors. Black and Bayer (1986), Knoeppel and Schauenburg (1989), and Tichenor (1989) report data on the release of these volatile organic compounds (VOCs). Field studies show that such products contribute significantly to indoor pollution; however, a large variety of compounds is in use, and few studies have been made that allow calculation of typical emission rates. Pesticides, both those applied indoors and those applied outdoors to control termites, also pollute building interiors.

Tobacco smoke is a prevalent and potent source of indoor air pollutants in residences, but not as much of a pollutant source in commercial buildings. Traditionally, almost all tobacco smoke arises from cigarette smoking. **Environmental tobacco smoke (ETS)**, sometimes called secondhand smoke, is the aged and diluted combination of sidestream smoke (smoke from the lit end of a cigarette and smoke that escapes from the filter between puffs) and mainstream smoke (smoke exhaled by a smoker). With the increasing popularity of the use of **electronic smoking devices ("e-cigarettes")** and cannabis legalization in some jurisdictions, ASHRAE *Standard* 62.1 (2016) extended its definition of ETS to include smoke produced from combustion of cannabis and controlled substances, and the emissions produced by electronic smoking devices. E-cigarette regulations differ across jurisdictions. The effects of tobacco smoke have been well studied: emission factors for ETS components, the ratio of ETS components to marker compounds, and apportionment of ETS components in indoor air are reported in the literature by Heavner et al. (1996), Hodgson et al. (1996), Martin et al. (1997), and Nelson et al. (1994). The emission profiles, exposure, and health risks of e-cigarette use are the subject of recent studies (Cooke et al. 2015; Herrington and Myers 2014; Pisinger and Døssing 2014). However, the available data are limited and often inconsistent, indicating a need for further research. Some background information on e-cigarettes can be found in Baker (2016).

Occupants, both humans and animals, emit a wide array of pollutants by breath, sweat, and flatus. Some of these emissions are conversions from solids or liquids within the body. Many volatile organics emitted are, however, reemissions of pollutants inhaled earlier, with the tracheobronchial system acting like a physical adsorber for gases, or as a filter for particles.

Floor dust, which typically contains much larger particles and fibers than the air, has been found to be a sink (adsorption medium) and secondary emission source for VOCs. Floor dust is a mixture of organic and inorganic particles, hair and skin scales, and textile fibers. The fiber portion of floor dust has been shown to contain as much as 169 mg/kg TVOC, and the particle portion 148 mg/kg (Gyntelberg et al. 1994). These VOCs were correlated to the prevalence of irritative (sore throat) and cognitive (concentration problems) symptoms among building occupants. One hundred eighty-eight compounds were identified from thermal desorption of office dust at 121°C (Wilkins et al. 1993). Household dust was found to be similar in composition (Wolkoff and Wilkins 1994).

Contaminants from other sources include chloroform from water; tetrachloroethylene and 1,1,1-trichloroethane from cleaning solvents; methylene chloride from paint strippers, fresheners, cleaners,

Licensed for single user. © 2021 ASHRAE, Inc.

and polishers; α-pinene and limonene from floor waxes; and 1-methoxy-2-propanol from spray carpet cleaners. Formaldehyde, a major VOC, has many sources, but pressed-wood products appear to be the most significant.

4.4 FLAMMABLE GASES AND VAPORS

Use of flammable materials is widespread. Flammable gases and vapors (as defined in NFPA *Standard* 30) can be found at hazardous levels in sewage treatment plants, sewage and utility tunnels, dry-cleaning plants, automobile garages, and industrial finishing process plants.

A flammable liquid's vapor pressure and volatility or rate of evaporation determine its ability to form an explosive mixture. These properties can be expressed by the **flash point**, which is the temperature to which a flammable liquid must be heated to produce a flash when a small flame is passed across the surface of the liquid. Depending on the test methods, either the open- or closed-cup flash point may be listed. The higher the flash point, the more safely the liquid can be handled. Liquids with flash points higher than 38°C are called **combustible**, whereas those under 38°C are described as **flammable**. Those with flash points less than 21°C should be regarded as highly flammable.

In addition to having a low flash point, the air/vapor or air/gas mixture must have a concentration in the flammable (explosive) range before it can be ignited. The **flammable (explosive) range** is the range between the upper and lower explosive limits, expressed as percent by volume in air. Concentrations of material above the higher range or below the lower range will not explode. Flashpoint and explosive range data for many chemicals are listed in the *Fire Protection Guide to Hazardous Materials*, published by the National Fire Protection Association (NFPA 2010). Data for a small number of representative chemicals are shown in Table 14.

In designing ventilation systems to control flammable gases and vapors, the engineer must consider the following.

Most safety authorities and fire underwriters prefer to limit concentrations to 20 to 25% of the lower explosive limit of a material. The resulting safety factor of 4 or 5 allows latitude for imperfections in air distribution and variations of temperature or mixture and guards against unpredictable or unrecognized sources of ignition. Operation at concentrations above the upper explosive limit should be allowed only in rare instances, and after taking appropriate precautions. Some guidance is provided in American Petroleum Institute documents [e.g., API (2009)]. To reach the upper explosive limit, the flammable gas or vapor must pass through the active explosive range, in which any source of ignition can cause an explosion. In addition, a drop in gas concentration caused by unforeseen dilution or reduced evaporation rate may place a system in the dangerous explosive range.

In occupied places where ventilation is applied for proper health control, the danger of an explosion is minimized. In most instances, flammable gases and vapors are also toxic, and maximum allowable concentrations are far below the material's lower explosive limit (LEL). For example, proper ventilation for acetone vapors keeps the concentration below the occupational exposure limit of 500 ppm (0.05% by volume). Acetone's LEL is 2.5% by volume. Proper location of exhaust and supply ventilation equipment depends primarily on how a contaminant is given off and on other problems of the process, and secondarily on the relative density of flammable vapor.

If the specific density of the explosive mixture is the same as that of air, cross drafts, equipment movement, and temperature differentials may cause sufficient mixing to produce explosive concentrations and disperse these throughout the atmosphere. In reasonably still air, heavier-than-air vapors may pool at floor level. Therefore, the engineer must either provide proper exhaust and supply air patterns to control hazardous material, preferably at its source, or offset the effects of drafts, equipment movement, and convection currents by providing good distribution of exhaust and supply air for general dilution and exhaust. The intake duct should be positioned so that it does not bring in exhaust gases or emissions from ambient sources.

Table 14 Flammable Limits of Some Gases and Vapors

Gas or Vapor	Flash Point,* °C	Flammable Limits, % by Volume	
		Lower	Upper
Acetone	–18	2.5	12.8
Ammonia	Gas	15	28
Benzene (benzol)	–11	1.2	7.8
n-Butane	–32	1.9	8.5
Carbon disulfide	–30	1.3	50
Carbon monoxide	Gas	12.5	74
1,2-Dichloroethylene	2	5.6	12.8
Diethylether	–45	1.9	36
Ethyl alcohol	13	3.3	19
Ethylene	Gas	2.7	36
Gasoline	–43	1.4	7.6
Hydrogen	Gas	4.0	75
Hydrogen sulfide	Gas	4.3	44
Isopropyl alcohol	12	2.0	12.7
Methyl alcohol	11	6.0	36
Methyl ethyl ketone	–9	1.4	11.4
Natural gas (variable)	Gas	3.8 to 6.5	13 to 17
Naphtha	Less than –18	1.1	5.9
Propane	Gas	2.1	9.5
Toluene (toluol)	4	0.1	7.1
o-Xylene	32	0.9	6.7

*Measured by closed-cup method

Adequate ventilation minimizes the risk of or prevents fires and explosions and is necessary, regardless of other precautions, such as elimination of the ignition sources, safe building construction, and the use of automatic alarm and extinguisher systems.

Chapter 32 of the 2019 *ASHRAE Handbook—HVAC Applications* gives more details about equipment for control of combustible materials. Some design, construction, and ventilation issues are also addressed by NFPA *Standard* 30.

4.5 COMBUSTIBLE DUSTS

Many organic and some mineral dusts can produce dust explosions (Bartnecht 1989). Explosive dusts are potential hazards whenever uncontrolled dust escapes, and often, a primary explosion results from a small amount of dust in suspension that has been exposed to a source of ignition. Explosibility limits for combustible dusts differ from those for flammable gases and flammable vapors because of the interaction between dust layers and suspended dust. In addition, the pressure and vibration created by an explosion can dislodge large accumulations of dust on horizontal surfaces, creating a larger secondary explosion.

For ignition, dust clouds require high temperatures and sufficient dust concentration. These temperatures and concentrations and the minimum spark energy can be found in Avallone et al. (2007). Several methods can be used to prevent ignition of dust material (Jaeger and Siwek 1999; Siwek 1997):

- Limit the temperature of deposited product.
- Avoid potentially explosive combustible substance/air mixtures.
- Introduce inert gas in the area to lower the oxygen volume content below the limiting oxygen concentration (LOC) or maximum allowable oxygen concentration (MOC), so that ignition of the mixture cannot occur. Adding inert dusts (e.g., rock salt, sodium sulfate) also works; in general, inert dust additions of more than 50% by mass are necessary. It is also possible to

Licensed for single user. © 2021 ASHRAE, Inc.

replace flammable solvents and cleaning agents with nonflammable halogenated hydrocarbons or water, or flammable pressure transmission fluids with halocarbon oils.
- Avoid effective ignition sources: eliminate heat sources (hot surfaces or smoldering material) and sources of sparks or electrostatic discharge.

Proper exhaust ventilation design can also be used for preventing high-dust conditions. Forced ventilation allows use of greater amounts of air and selective air circulation in areas surrounding the equipment. Its use and calculation of the minimum volume flow rate for supply and exhaust air are subject to certain requirements, covered in Chapter 32 of the 2019 *ASHRAE Handbook—HVAC Applications.* Ventilation systems and equipment chosen must prevent dust pocketing inside the equipment. When local exhaust ventilation is used, separation equipment should be installed as close to the dust source as possible to prevent transport of dust in the exhaust system.

4.6 RADIOACTIVE AIR CONTAMINANTS

Radioactive contaminants (Jacobson and Morris 1977) can be particulate or gaseous in nature. Many radioactive materials would be chemically toxic if present in high concentrations; however, in most cases, the radioactivity necessitates limiting their concentration in air.

Most radioactive air contaminants affect the body when they are absorbed and retained. This is known as the **internal radiation hazard**. Airborne radioactive particulates can eventually enter the food chain and thus the human body. Radioactive material deposited on the ground increases **external radiation exposure**. However, except for fallout from nuclear weapons or a serious reactor accident, such exposure is insignificant.

Radioactive air contaminants can emit alpha, beta, or gamma rays. **Alpha rays**, although of higher energy, penetrate tissue poorly and present no hazard, except when the material is deposited inside or on the body. **Beta rays** are somewhat more penetrating and can be both an internal and an external hazard. Penetration of **gamma rays** depends on their energy, which varies with radioactive element or isotope.

There is a distinction between the radioactive material itself and the radiation it emits. Radioactive materials present distinctive problems. High concentrations of radioactivity can generate enough heat to damage filtration equipment or ignite the material spontaneously. Most radioactive materials are hazardous at much lower concentrations than those for ordinary materials; thus, special electronic instruments that respond to radioactivity must be used to detect these hazardous levels.

Radioactive particles can be removed from air by devices such as HEPA and ULPA filters, and radioactive gases by impregnated carbon or alumina and absorption traps, but the gamma radiation from such collected material can penetrate outside of the material. This distinction is frequently overlooked.

The amount of radioactive material in air is measured in becquerels (Bq) per cubic metre [1 Bq = 27.027 picocuries (pCi)], and the dose of radiation from deposited material is measured in gray.

The ventilation engineer faces difficulty in dealing with radioactive air contamination because of the extremely low permissible concentrations for radioactive materials. For some sensitive industrial plants, such as those in the photographic industry, contaminants must be kept from entering the plant. If radioactive materials are handled inside the plant, the problem is to collect the contaminated air as close to the source as possible, and then remove the contaminant from the air with a high degree of efficiency, before discharging the air to the outdoors. Filters are generally used for particulate materials, but venturi scrubbers, wet washers, and other devices can be used as prefilters to meet special needs.

Design of equipment and systems for control of radioactive particulates and gases in nuclear laboratories, power plants, and fuel-processing facilities is a highly specialized technology. Careful attention must be given to the reliability, as well as the contaminant-removal ability, of equipment under the special environmental stresses involved. More information on these procedures can be found in Chapter 46 of the 2019 *ASHRAE Handbook—HVAC Applications* and in various publications of the U.S. Department of Energy [see, e.g., DOE (2006)].

Radon

A major source of airborne radioactive exposure to the population comes from radon. Radon (Rn) is a naturally occurring, chemically inert, colorless, odorless, tasteless radioactive gas. It is produced from radioactive decay of radium, which is formed through several intermediate steps of decay of uranium and thorium. Radon is widely found in the natural environment, because uranium salt precursors are widespread. Radon-222 is the most common isotope of radon. The EPA has developed a map of the United States that shows predicted radon concentrations throughout the country (EPA 2016c).

As a gas, radon (before it decays) can move limited distances through very small spaces, such as those between particles of soil and rock, and enter indoor environments (Nazaroff et al. 1988; Tanner 1980). Additional but secondary sources of indoor radon include groundwater (radon is quite soluble in water) and radium-containing building materials.

Radon gas enters a house or building primarily through cracks, joints, and other holes in concrete foundations; directly through porous concrete blocks; through joints and openings in crawlspace ceilings; and through leakage points in HVAC ductwork embedded in slab floors or located in crawlspaces. Pressure-driven flow is the dominant radon entry mechanism in houses with elevated radon concentrations (Nazaroff et al. 1987). Pressure differences are caused by several factors, including thermal stack effect, wind, and operation of HVAC equipment. Rn can also diffuse directly through substructural materials (e.g., concrete). The diffusive Rn entry rate is often a significant portion of the total entry rate into residences.

Typical Radon Levels. The outdoor radon concentration is about 15 Bq/m^3 (0.4 pCi/L). The annual average concentration of radon in U.S. homes is about 46 Bq/m^3 (1.25 pCi/L) (EPA 1989). Although several sources of radon may contribute to the annual indoor average, pressure-driven flow of soil gas is the principal source for elevated concentrations. Nonmunicipal water supplies can be a source of elevated indoor radon, but only in isolated instances.

Measurement Methods. Indoor concentrations of radon can vary hourly, daily, and seasonally by a factor of 10 to 20 (Turk et al. 1990). Thus, long-term measurements (3 months to 1 year) generally provide more reliable estimates of the average indoor concentration. Two widely used techniques are the short-term charcoal canister (measuring for up to 7 days), and the long-term alpha-track methods (kept in place for 90 days to 1 year). Generally, short-term measurements should only be used as a screening technique to determine whether long-term measurement is necessary. When interpreting the results, consider the great uncertainties in measurement accuracy with these devices (up to 50% at the radon levels typically found in homes), as well as the natural variability of radon concentrations.

Ideally, long-term measurements should be the basis for decisions about installing radon mitigation systems, and short-term measurements should only be used as a screening method to identify buildings with radon concentrations that are very high, justifying immediate remedial action. In practice, short-term measurements at the time a building is sold are the basis for most decisions about remedial action.

Licensed for single user. © 2021 ASHRAE, Inc.

Control. Exposure to indoor radon may be reduced by (1) inhibiting its entry into the building or (2) removing or diluting radon decay products in indoor air. The most effective and energy-efficient control measures are generally those that reduce radon entry rates (Henschel 1993). Chapter 46 of the 2019 *ASHRAE Handbook—HVAC Applications* provides more detail on these measures.

4.7 SOIL GASES

The radioactive gas radon (Rn) is the best-known soil gas, but other gaseous contaminants may enter buildings along with radon from surrounding soil. Methane from landfills has reached explosive levels in some buildings. Potentially toxic or carcinogenic VOCs, including chlorinated hydrocarbons in the soil because of spills, improper disposal, leaks from storage tanks, and disposal in landfills, can also be transported into buildings (Garbesi and Sextro 1989; Hodgson et al. 1992; Kullman and Hill 1990; Wood and Porter 1987). Pesticides applied to soil beneath or adjacent to houses have also been detected in indoor air (Livingston and Jones 1981; Wright and Leidy 1982). The broad significance of health effects of exposure to these soil contaminants is not well understood.

Although soil gases generally have limited effects when diffusion is the primary mechanism driving entry, there are situations where advective processes are dominant. In such cases, effects on indoor air can be significant (Adomait and Fugler 1997). Pressure-driven airflow produced by thermal or wind drivers on the building affects entry of soil gas into the structure. Soil permeability to vapors, soil gas concentration, and soil-to-building pressure differential are the largest factors influencing indoor concentrations of these gases.

Techniques that reduce Rn entry from soil should also be effective in reducing entry of other soil gases into buildings. Other approaches (e.g., increasing ventilation in the building, such as by slightly opening a window) may help reduce house negative pressure (created by stack effect) with respect to soil gas pressure. Increased ventilation should be used with caution, and only after establishing for the house in question that it will not increase negative pressure where the soil gas enters.

CHAPTER 12

ODORS

Odor Sources 12.1
Sense of Smell 12.1
Factors Affecting Odor Perception 12.2
Odor Sensation Attributes 12.3
Dilution of Odors by Ventilation 12.5
Odor Concentration 12.5
Olf Units 12.6

VARIOUS factors make odor control an important consideration in ventilation engineering: (1) contemporary construction methods result in buildings that allow less air infiltration through the building envelope; (2) indoor sources of odors associated with modern building materials, furnishings, and office equipment have increased; (3) outdoor air is often polluted; and (4) energy costs encourage lower ventilation rates at a time when requirements for a relatively odor-free environment are greater than ever.

Since Yaglou et al.'s (1936) classic studies, the philosophy behind ventilation of nonindustrial buildings has mainly been to provide indoor air that is acceptable to occupants. Air is evaluated by the olfactory sense, although the general chemical sense, which is sensitive to irritants in the air, also plays a role.

This chapter reviews how odoriferous substances are perceived. Chapter 47 of the 2019 *ASHRAE Handbook—HVAC Applications* covers control methods. Chapter 10 of this volume has more information on indoor environmental health.

1. ODOR SOURCES

Outdoor sources of odors include automotive and diesel exhausts, hazardous waste sites, sewage treatment plants, compost piles, refuse facilities, printing plants, refineries, chemical plants, and many other stationary and mobile sources. These sources produce both inorganic compounds (e.g., ammonia and hydrogen sulfide) and volatile organic compounds (VOCs), including some that evaporate from solid or liquid particulate matter. Odors emitted by outdoor sources eventually enter the indoor environment.

Indoor sources also emit odors. Sources include tobacco products, bathrooms and toilets, building materials (e.g., adhesives, paints, caulks, processed wood, carpets, plastic sheeting, insulation board), consumer products (e.g., food, toiletries, cleaning materials, polishes), hobby materials, fabrics, and foam cushions. In offices, offset printing processes, copiers, and computer printers may produce odors. Electrostatic processes may emit ozone. Humans emit a wide range of odorants, including acetaldehyde, ammonia, ethanol, hydrogen sulfide, and mercaptans.

Mildew and other decay processes often produce odors in occupied spaces (home and office), damp basements, and ventilation systems (e.g., from wetted air-conditioning coils and spray dehumidifiers).

Chapter 47 of the 2019 *ASHRAE Handbook—HVAC Applications* gives further information on contaminant sources and generation rates.

2. SENSE OF SMELL

Olfactory Stimuli

Organic substances with relative molecular masses greater than 300 are generally odorless. Some substances with relative molecular masses less than 300 are such potent olfactory stimuli that they can be perceived at concentrations too low to be detected with direct-reading instruments. Trimethylamine, for example, can be recognized as a fishy odor by a human at a concentration of about 10^{-4} ppm.

Table 1 shows **odor detection threshold concentrations** for selected compounds. The **threshold limit value** (TLV) is the concentration of a compound that should have no adverse health consequences if a worker is regularly exposed for 8 h periods (ACGIH, revised annually). Table 1 also includes the ratio of the TLV to the odor threshold for each compound. For ratios greater than 1, most occupants can detect the odor and leave the area long before the compound becomes a health risk. As the ratio increases, the safety factor provided by the odor also increases. Table 1 is not a comprehensive list of the chemicals found in indoor air. AIHA (1989) and EPA (1992) list odor thresholds for selected chemicals.

Olfactory sensitivity often makes it possible to detect potentially harmful substances at concentrations below dangerous levels so that they can be eliminated. Foul-smelling air is often assumed to be unhealthy. In reality, however, there is little correlation between odor perception and toxicity, and there is considerable individual variation in the perception of pleasantness/unpleasantness of odors. When symptoms such as nausea, headache, and loss of appetite are caused by an unpleasant odor, it may not matter whether the air is toxic but whether the odor is perceived to be unpleasant, associated

Table 1 Odor Thresholds, ACGIH TLVs, and TLV/Threshold Ratios of Selected Gaseous Air Pollutants

Compound	Odor Threshold,[a] ppmv	TLV,[b] ppmv	Ratio
Acetaldehyde	0.067	25-C	360
Acetone	62	500	8.1
Acetonitrile	1600	20	0.013
Acrolein	1.8	0.1-C	0.06
Ammonia	17	25	1.5
Benzene	61	0.5	0.01
Benzyl chloride	0.041	1	24
Carbon tetrachloride	250	5	0.02
Chlorine	0.08	0.5	6
Chloroform	192	10	0.05
Dioxane	12	20	1.7

with an unpleasant experience, or simply felt to be out of appropriate context. The magnitude of the symptoms is related to the magnitude of the odor, but even a room with a low but recognizable odor can make occupants uneasy. Several papers review sensory irritation and its relation to indoor air pollution (Cain and Cometto-Muñiz 1995; Cometto-Muñiz and Cain 1992; Cometto-Muñiz et al. 1997; Shams Esfandabad 1993).

Anatomy and Physiology

The **olfactory receptors** lie in the **olfactory cleft**, which is high in the nasal cavity. About five million olfactory **neurons** (a small cluster of nerve cells inside the nasal cavity above the bridge of the nose) each send an **axon** (an extension of the neuron) into the olfactory bulb of the brain. Information received from the receptors is passed to various central structures of the brain (e.g., olfactory cortex, hippocampus, amygdala). One sniff of an odorant can often evoke a complex, emotion-laden memory, such as a scene from childhood.

The surrounding nasal tissue contains other diffusely distributed nerve endings of the trigeminal nerve that also respond to airborne vapors. These receptors mediate the chemosensory responses such as tickling, burning, cooling, and, occasionally, painful sensations that accompany olfactory sensations. Most odorous substances at sufficient concentration also stimulate these nerve endings.

Olfactory Acuity

The olfactory acuity of the population is normally distributed. Most people have an average ability to smell substances or to respond to odoriferous stimuli, a few people are very sensitive or hypersensitive, and a few others are insensitive, including some who are totally unable to smell (**anosmic**). The olfactory acuity of an individual varies with the odorant.

Hormonal factors, which often influence emotional states, can modulate olfactory sensitivity. Although the evidence is not uniformly compelling, research has found that (1) the sensitivity of females varies during the menstrual cycle, reaching a peak just before and during ovulation (Schneider 1974); (2) females are generally more sensitive than males, but this difference only emerges around the time of sexual maturity (Koelega and Koster 1974); (3) sensitivity is altered by some diseases (Schneider 1974); and (4) various hormones and drugs (e.g., estrogen, alcohol) alter sensitivity (Engen et al. 1975; Schneider 1974).

Other factors that may affect olfactory perception include the individual's olfactory acuity, the magnitude of flow rate toward olfactory receptors, temperature, and relative humidity. Olfactory acuity can also vary with age (Stevens et al. 1989; Wysocki and Gilbert 1989), genetics (Wysocki and Beauchamp 1984), exposure history (Dalton and Wysocki 1996; Wysocki et al. 1997), and disease or injury (Cowart et al. 1993, 1997). Humans are able to perceive a large number of odors, yet untrained individuals are able to name only a few (Ruth 1986).

Individuals who are totally unable to detect odors are relatively rare (Cowart et al. 1997). A more common occurrence is an inability to detect one or a very limited number of odors, a condition known as **specific anosmia**. Although the huge number of possible chemicals makes for an untestable hypothesis, it has been posited that most, if not all, individuals have a specific anosmia to one or more compounds (Wysocki and Beauchamp 1984). The fact that individuals with specific anosmias have normal olfactory acuity for all other odors suggests that such anosmias may be caused by genetic differences.

In olfactory science, **adaptation** refers to decreased sensitivity or responsiveness to an odor after prolonged exposure. This exposure can selectively impair the perception of the exposure odorant, but there are also examples of cross-adaptation, where exposure to one odorant can result in adaptation to other odors as well. Adaptation can occur in the short term, where perception of a room's odor begins to fade within seconds of entering the room (Cometto-Muñiz and Cain 1995; Pierce et al. 1996). With long-term adaptation, an individual who habitually returns to the same environment does not smell odors that are quite discernible to a naive observer. This effect appears to shift both the threshold and the **suprathreshold** (stimuli above the threshold level) response to the odor (Dalton and Wysocki 1996). This is an important phenomenon for indoor air quality (IAQ) personnel to be aware of because it is often one of the biggest reasons for variations in detectability or response in real-world environments and makes the choice of test population or panelists for air quality evaluations a critical one.

3. FACTORS AFFECTING ODOR PERCEPTION

Humidity and Temperature

Temperature and humidity can both affect the perception of odors. Cain et al. (1983) reported that a combination of high temperature (25.5°C) and high humidity exacerbates odor problems. Berglund and Cain (1989) found that air was generally perceived to be fresher and less stuffy with decreasing temperature and humidity. Fang et al. (1998a, 1998b) and Toftum et al. (1998) found little or no increase in odor intensity with increasing enthalpy (temperature and humidity), but reported a very significant decrease in odor acceptability with increasing enthalpy.

Not all researchers have supported these findings. Kerka and Humphreys (1956) reported a decrease in odor intensity with increasing humidity. Berg-Munch and Fanger (1982) found no increase in odor intensity with increasing temperature (23 to 32°C). Clausen et al. (1985) found no significant change in odor intensity with increasing relative humidity (30% to 80%).

Although the findings are not homogeneous, they do show that temperature and humidity can act together to affect one's perception of odors. Air that is cooler and drier is generally perceived to be fresher and more acceptable even if odor intensity is not affected.

Sorption and Release of Odors

Because furnishings and interior surfaces absorb (and later desorb) odors during occupancy, spaces frequently retain normal occupancy odor levels long after occupancy has ceased. This is observed when furnaces or radiators, after a long shutdown, are heated at winter start-up and when evaporator coils warm up. The rate of desorption can be decreased by decreasing temperature and relative humidity, and increased (as for cleaning) by the reverse.

Environmental tobacco smoke may desorb from surfaces long after smoking has taken place. This phenomenon has caused many hotels to establish nonsmoking rooms.

Where the odor source is intrinsic to the materials (as in linoleum, paint, rubber, and upholstery), reducing the relative humidity decreases the rate of odor release. Quantitative values should not be used without considering the sorption/desorption phenomenon.

Emotional Responses to Odors

There can be considerable variation between individuals regarding the perceived pleasantness or unpleasantness of a given odor. Responses to odors may be determined by prior experiences and can include strong emotional reactions. This is because one of the brain structures involved in the sense of smell is the **amygdala**, a regulator of emotional behaviors (Frey 1995). Some IAQ complaints can involve emotional responses completely out of proportion to the concentration of the odorant or the intensity of the odor it produces.

Two theories describe physiological reasons for these strong responses. One of these is **kindling**, in which repeated, intermittent stimuli amplify nerve responses. The other is **response facilitation**, in which an initial stimulus perceived as strong is facilitated (becomes greater) rather than adapted to (Frey 1995).

Licensed for single user. © 2021, ASHRAE, Inc.

Because of this emotional aspect, IAQ complaints involving odors can be very difficult to solve, especially if they are coming from a few sensitized individuals. It is important to respond quickly to complaints to minimize the risk of kindling or response facilitation.

4. ODOR SENSATION ATTRIBUTES

Odor sensation has four components or attributes: detectability, intensity, character, and hedonic tone.

Detectability (or **threshold**) is the minimum concentration of an odorant that provokes detection by some predetermined segment of the population. Two types of thresholds exist: detection and recognition.

The **detection threshold** is the lowest level that elicits response by a segment of the population. If that segment is 50%, the detection threshold is denoted by ED_{50}. **Recognition threshold** is the lowest level at which a segment of the population can recognize a given odor. Thresholds can be attributed to 100%, which includes all olfactory sensitivities, or to 10%, which includes only the most sensitive segment of the population. Threshold values are not physical constants, but statistical measurements of best estimates.

Intensity is a quantitative aspect of a descriptive analysis, stating the degree or magnitude of the perception elicited. Intensity of the perceived odor is, therefore, the strength of the odoriferous sensation. Detection threshold values and, most often, odor intensity determine the need for indoor odor controls.

Character defines the odor as similar to some familiar smell (e.g., fishy, sour, flowery). **Hedonics**, or the hedonic tone of an odor, is the degree to which an odor is perceived as pleasant or unpleasant. Hedonic judgments include both a *category* judgment (pleasant, neutral, unpleasant) and a *magnitude* judgment (very unpleasant, slightly pleasant).

Important questions are

- What is the minimum concentration of odorant that can be detected?
- How does perceived odor magnitude grow with concentration above the threshold?

No universal method has been accepted to measure either the threshold or perceived magnitude of the odor above threshold. However, guidelines and conventions simplify the choice of methods.

Detectability

Perception of weak odoriferous signals is probabilistic: at one moment odor may be perceptible, and at the next moment it may not. Factors affecting this phenomenon include moment-to-moment variability in the number of molecules striking the olfactory receptors, variability in which of the receptors are stimulated, concentration of the odor, the individual's style of breathing, and the individual's previous experience with the odor. The combined effect of these factors may prevent an individual from perceiving an odor during the entire time of the stimulus. During odor evaluation, dilution to detection or recognition threshold values allows determination of the largest number of dilutions that still allows half of the panelists to detect or recognize the odor.

Determination of Odor Thresholds. Odor threshold testing is over a century old. The process is complex, and several different methods are used. Partly because of variations in measurement techniques, reported threshold values can vary by several orders of magnitude for a given substance. To minimize variation caused by experimental techniques, a standard set of criteria has been developed for the panel, presentation apparatus, and presentation method (AIHA 1989; EPA 1992).

The **panel** should

- Include at least six members per group.
- Be selected based on odor sensitivity. Factors to be considered include anosmia, pregnancy, drug use, and smoking.
- Be calibrated to document individual and group variability.

Considerations for the **presentation apparatus** include

- Vapor modality: choice of a gas/air mixture, water vapor, or other substance.
- Diluent: choice of diluent (e.g., air, nitrogen), how it is treated, and what its source is.
- Presentation mode: delivery systems can be nose ports, vents into which the head is inserted, flasks, or whole rooms.
- Analytic measurement of odorant concentration.
- System calibration: flow rate should be approximately 0.05 L/s; face velocity should be low enough to be barely perceptible to the panelists.

Criteria for the **presentation method** include

- Threshold type: detection or recognition.
- Concentration presentation: this must take adaptation into account. Presenting ascending concentrations or allowing longer periods between concentrations helps avoid adaptation.
- Number of trials: test/retest reliability for thresholds is low. Increasing the number of trials helps correct for this.
- Forced-choice procedure: panelists must choose between the stimuli and one or two blanks. This helps eliminate false positive responses.
- Concentration steps: odorant should be presented successively at concentrations no more than three times the preceding one.

For more details regarding psychophysical procedures, ways to sample odoriferous air, handling samples, means of stimulus presentation, and statistical procedures, consult ASTM (1996).

Intensity

Psychophysical Power Law. The relation between **perceived odor magnitude *S*** and **concentration *C*** conforms to a power function:

$$S = kC^n \tag{1}$$

where

S = perceived intensity (magnitude) of sensation
k = characteristic constant
C = odorant concentration
n = exponent of psychophysical function (slope on a log-log scale)

This exemplifies the psychophysical power law, also called **Stevens' law** (Stevens 1957). In the olfactory realm, $n < 1.0$. Accordingly, a given percentage change in odorant concentration causes a smaller percentage change in perceived odor magnitude.

Scaling Methods. There are various ways to scale perceived magnitude, but a **category scale**, which can be either number- or word-categorized, is common. Numerical values on this scale do not reflect ratio relations among magnitudes (e.g., a value of 2 does not represent a perceived magnitude twice as great as a value of 1). Table 2 gives four examples of category scales.

Although category scaling procedures can be advantageous in the field, **ratio scaling** is used frequently in the laboratory (Cain and Moskowitz 1974). Ratio scaling requires observers to assign numbers proportional to perceived magnitude. For example, if the observer is instructed to assign the number 10 to one concentration and a subsequently presented concentration seems three times as strong, the observer calls it 30; if another seems half as strong, the observer assigns it 5. This procedure, called **magnitude estimation**, was used to derive the power function for butanol (Figure 1). Ratio scaling techniques allow for such relationships because they require subjects to produce numbers to match perceived sensations in which the numbers emitted reflect the ratio relations among the sensations.

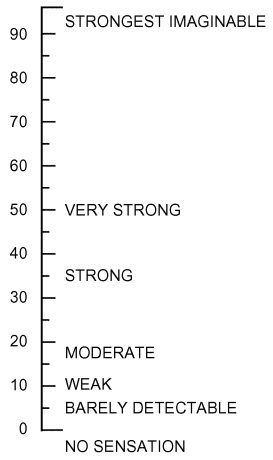
(Moskowitz et al. 1974)

Table 2 Examples of Category Scales

Number Category		Word Category	
Scale I	**Scale II**	**Scale I**	**Scale II**
0	0	None	None at all
1	1	Threshold	Just detectable
2	2.5	Very slight	Very mild
3	5	Slight	Mild
4	7.5	Slight-moderate	Mild-distinct
5	10	Moderate	Distinct
6	12.5	Moderate-strong	Distinct-strong
7	15	Strong	Strong



Source: Meilgaard et al. (1987).

The **labeled magnitude scale** is a hybrid of category and ratio scales (Green et al. 1996). This scale is intended to yield ratio-level data with a true zero and an orderly relationship among the scale values, such that any stimulus can be expressed as being proportionately more or less intense than another. Because it allows subjects to use natural-language descriptors to scale perceived experience, it often requires less training than ratio scales and produces absolute intensity estimates of perceived sensation (Figure 2).

A fourth way to measure suprathreshold odor intensity is to **match the intensity of odorants**. An observer can be given a concentration series of a matching odorant (e.g., 1-butanol) to choose the member that matches most closely the intensity of an *unknown* odorant. The matching odorant can be generated by a relatively inexpensive olfactometer such as that shown in Figure 3. Figure 4 shows, in logarithmic coordinates, functions for various odorants obtained by matching (Dravnieks and Laffort 1972). The left-hand ordinate expresses intensity in terms of concentration of butanol, and the right-hand ordinate expresses intensity in terms of perceived magnitude. The two ordinates are related by the function in Figure 1, the standardized function for butanol. The matching method illustrated here has been incorporated into ASTM *Standard* E544.

Character

The quality or character of an odor is difficult to assess quantitatively. A primary difficulty is that odors can vary along many dimensions. One way to assess quality is to ask panelists to judge the similarity between a test sample and various reference samples, using a five-point category scale. For some applications, reference odorants can be chosen to represent only the portion of the qualitative range relevant to the problem under investigation (e.g., animal odors). Another procedure is to ask panelists to assess the degree of

Subjects use a cursor (on a computer screen) or a pencil to mark the location on the scale that represents their judgment of intensity. They do not see numbers, only labels, and can place the mark anywhere on the scale.

association between a test sample's quality and certain verbal descriptors (e.g., sweaty, woody, chalky, sour).

The number of odorant descriptors and descriptors to be used have been subjects of disagreement (Harper et al. 1968). The number of descriptors varies from a minimum of seven (Amoore 1962) to as many as 830 used by an ASTM subcommittee. An atlas of odor characters, containing 146 descriptors, was compiled for 180 chemicals by ASTM (1985).

An odor can be characterized either by an open-ended word description or by multidimensional scaling. **Multidimensional scaling** is based on similarity and dissimilarity judgments in comparison to a set of standard odors or to various descriptors.

In some cases, the interest may be merely whether an odor's quality has changed as a result of some treatment (e.g., use of a bacteriostat). Under these circumstances, samples of air taken before and after treatment can be compared directly (using a simple scale of similarity) or indirectly (with appropriate verbal descriptors).

Hedonics

The acceptability or pleasantness of an odor can be measured psychophysically in the same way as odor intensity. Both ratio and category scaling procedures can be adapted to odor acceptability.

Odors do not always cause adverse reactions. Products are manufactured to elicit favorable responses. Acceptance tests may involve product comparison (frequently used in the perfume industry) or a hedonic scale. The premise of acceptance tests is that the larger the segment of subjects accepting the odor, the better the odor. A hedonic scale that allows for negative as well as positive responses is likely to better determine how acceptable the odor is.

All persons exposed to a given odor are not likely to agree on its acceptability. Acceptability of a given odor to a person is based on a complex combination of associations and is not simply a characteristic of the odor itself (Beck and Day 1991). Responses to odors are determined by both **bottom-up factors** (attributes or properties of the odorant) and **top-down factors** (expectations, attitudes, and associations from prior experience stored in memory, and appropriateness of the odor in its present context). Both factors are activated when an individual detects an odor, and the individual's ultimate response (e.g., perception of intensity, hedonics, irritation, or symptoms) is a joint function of both (Dalton 1996; Dalton et al. 1997). In some cases, the interpretation provided by the top-down process appears to override the outcome from the bottom-up process, resulting in complaints, symptoms, and reports of illness.

5. DILUTION OF ODORS BY VENTILATION

The size of the exponent n in Stevens' law [Equation (1)] varies from one odorant to another, ranging from less than 0.2 to about 0.7 (Cain and Moskowitz 1974). This determines the **slope** or **dose response** of the odor intensity/odorant concentration function and has important consequences for malodor control. A low slope value indicates an odor that requires greater relative dilution for the odor to dissipate; a high slope value indicates an odor that can be more quickly reduced by ventilation. For example, an exponent of 0.7 implies that, to reduce perceived intensity by a factor of 5, the concentration must be reduced by a factor of 10; an exponent of 0.2 would require a reduction in concentration by a factor of more than 3000 for the same reduction in perceived magnitude. Examples of compounds with low slope values include hydrogen sulfide, butyl acetate, and amines. Compounds with high slope values include ammonia and aldehydes.

The ability of ventilation to control odors also depends on the strength of the source generating the odorant(s) and the nature of the odor. An odorant with a stronger source requires proportionately more ventilation to achieve the same reduction in concentration. Odors that are perceived as unpleasant may require substantially greater reduction before being perceived as acceptable. In addition, some sources, such as painted walls and flooring materials, may show increased emission rates in response to increased ventilation rates, which further complicates the issue (Gunnarsen 1997).

6. ODOR CONCENTRATION

Analytical Measurement

Performance data on control of specific odorants can be obtained using suitable analytical methods. Detectors can sense substances in amounts as little as 1 ng. Air contains many minor components, so gas chromatographic separation of the components must precede detection. Because odor thresholds for some compounds are low, preconcentration of the minor components is necessary. **Preconcentration** consists of adsorption or absorption by a stable, sufficiently nonvolatile material, followed by thermal desorption or extraction. NIOSH (1993) reviews techniques for sampling and analysis of VOCs in indoor air.

Mass spectrometry can be used with **gas chromatography** to identify constituents of complex mixtures. The chromatograph resolves a mixture into its constituents, and the spectrometer provides identification and concentration of selected constituents.

Several other detectors are sufficiently sensitive and specific to detect resolved components. **Hydrogen flame ionization detectors** respond adequately and nearly mass-proportionally to almost all hydrocarbons, though their responses to organic chemicals containing other atoms (e.g., oxygen) are more variable. **Flame photometric detectors** can pinpoint with equal sensitivity compounds that contain sulfur; many sulfur compounds are strongly odorous and are of interest in odor work. A **Coulson conductometric detector** is specifically and adequately sensitive to ammonia and organic nitrogen compounds. **Thermal conductivity detectors** are generally not sensitive enough for analytical work on odors.

Frequently, a **sniffing port** (Dravnieks and Krotoszynski 1969; Dravnieks and O'Donnell 1971) is installed in parallel with the detector(s). Part of the resolved effluent exhausts through the port and allows components that are particularly odorous or carry some relevant odor quality to be annotated. Usually, only a fraction of all components studied exhibits odors.

Airborne VOCs cause odors, but the correlation between indoor VOC concentrations and odor complaints in indoor environments is poor. Considerable work has been done on **artificial noses**, which may offer objective determination of odorants (Bartlett et al. 1997; Freund and Lewis 1995; Moy et al. 1994; Taubes 1996). However, because the physicochemical correlates of olfaction are poorly understood, no simple analytical means to predict an odorant's perceived quality and intensity exists. Moreover, because acceptability of an odorant depends strongly on context, it is unlikely that analytical instruments will supplant human evaluation.

Odor Units

Odor concentration can be expressed as the number of unit volumes that a unit volume of odorous sample occupies when diluted to the odor threshold with nonodorous air. If a sample of odorous air can be reduced to threshold by a tenfold dilution with pure air, the concentration of the original sample is said to be 10 odor units. Hence, odor units are equivalent to multiples of threshold concentrations. Odor units are not units of perceived magnitude.

Odor units are widely used to express legal limits for emission of odoriferous materials. For example, the law may state that a factory operation may not cause the ambient odor level to exceed 15 odor units. For every odorant (chemical), odor units and parts per million (ppm) are proportional. The proportionality constant varies from one odorant to another, depending on the number of ppm needed to evoke a threshold response. Perceived odor magnitude (intensity), however, does not grow proportionally with concentration expressed in

Licensed for single user. © 2021, ASHRAE, Inc.

ppm. Therefore, it cannot grow proportionally with concentration expressed in odor units. For example, a sample of 20 odor units is always perceived as less than twice as strong as a sample of 10 odor units. Moreover, because the psychophysical function (slope) varies from one odorant to another, samples of two odorants, each at 20 odor units, may have unequal perceived intensities.

Although odor units are not equivalent to units of perceived magnitude, they can be useful. Most indoor and outdoor contaminants are complex mixtures, so that the actual concentration of the odoriferous portion of a sample cannot be expressed with certainty. Thus, the odor unit is a useful measure of concentration of the mixture when evaluating, for example, the efficiency of a filter or ventilation system to remove or dilute the odor.

7. OLF UNITS

Sometimes IAQ scientists cannot successfully resolve complaints about air in offices, schools, and other nonindustrial environments. Customarily, complaints are attributed to elevated pollutant concentrations; frequently, however, such high concentrations are not found, yet complaints persist.

Assuming that the inability to find a difference between air pollutant levels in buildings with registered complaints and those without complaints is due to inadequacies of prevailing measurement techniques, Fanger and others changed the focus from chemical analysis to sensory analysis (Fanger 1987, 1988; Fanger et al. 1988). Fanger quantified air pollution sources by comparing them with a well-known source: a sedentary person in thermal comfort. A new unit, the **olf**, was defined as the emission rate of air pollutants (bioeffluents) from a standard person. A **decipol** is one olf ventilated at a rate of 10 L/s of unpolluted air.

To use these units, Fanger generated a curve that relates the percentage of persons dissatisfied with air polluted by human bioeffluents as a function of the outdoor air ventilation rate and obtained the following expression:

$$D = 395\exp(-3.66q^{0.36}) \quad \text{for} \quad q \geq 0.332$$
$$D = 100 \quad \text{for} \quad q < 0.332 \qquad (2)$$

where

D = percentage of persons dissatisfied
q = ventilation/emission ratio, L/s per olf

This curve (Figure 5) is based on experiments involving more than 1000 European subjects (Fanger and Berg-Munch 1983). Experiments with American (Cain et al. 1983) and Japanese (Iwashita et al. 1990) subjects show very similar results.

The idea behind the olf is to express both human and nonhuman sensory sources in a single unit: equivalent standard persons (i.e., in olfs). A room should therefore be ventilated to handle the total sensory load from persons and building. The olf concept is used in European publications for ventilation (CEN 1998; ECA 1992) to determine required ventilation and in several national standards, including the Norwegian Building Code. Table 3 shows the sensory loads from different pollution sources used in CEN (1998).

Example. Office, low-polluting building, occupancy 0.07 persons/m^2.

Occupants	0.07 olf/m^2
Building	0.1 olf/m^2
Total sensory load	0.17 olf/m^2

30% dissatisfied requires 4 L/s per olf ventilation rate (Figure 5).
Required ventilation: $4 \times 0.17 = 0.7$ L/(s·m^2).

The sensory load on the air in a space can be determined from Figure 5 by measuring the outdoor ventilation rate and determining the percent dissatisfied, using an untrained panel with a minimum of 20 impartial persons (Gunnarsen and Fanger 1992). The panel judges the acceptability of the air just after entering the space. The required ventilation rate depends on the desired percentage of occupant satisfaction. In ASHRAE *Standard* 62.1, 80% acceptability (20% dissatisfied) is the goal; European guidelines offer three quality levels: 15%, 20%, and 30% dissatisfied.

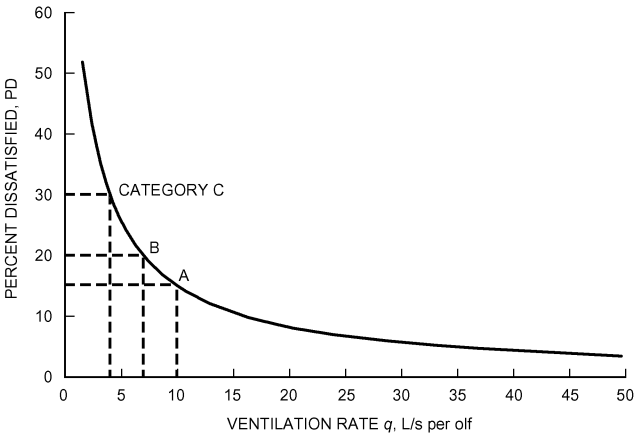

Fig. 5 Percentage of Dissatisfied Persons as a Function of Ventilation Rate per Standard Person (i.e., per Olf)
(CEN 1998)

Table 3 Sensory Pollution Load from Different Pollution Sources

Source	Sensory Load
Sedentary person (1 to 1.5 met)	1 olf
Person exercising	
Low level (3 met)	4 olf
Medium level (6 met)	10 olf
Children, kindergarten (3 to 6 yrs)	1.2 olf
Children, school (4 to 16 yrs)	1.3 olf
Low-polluting building	0.1 olf/m^2
Non-low-polluting building	0.2 olf/m^2

Source: CEN (1998).

Although this system has much to offer from a theoretical standpoint, its use is controversial in some areas. Problems have been found in cultural differences among panel members and access to outdoor air for dilution (Aizlewood et al. 1996). The trend is now to use untrained panels, as described in the previous paragraph. Knudsen et al. (1998) showed that, for some building materials, the curve giving the relation between percent dissatisfied and ventilation rate is less steep than that in Figure 5, whereas it is steeper for others. The sensory load in this case depends on the ventilation rate. The constant sensory loads in Table 3 should therefore be seen as a first approximation.

THIS chapter presents two common indoor environmental modeling methods to calculate airflows and contaminant concentrations in buildings: computational fluid dynamics (CFD) and multizone network airflow modeling. Discussion of each method includes its mathematical background, practical modeling advice, model validation, and application examples.

Each modeling method has strengths and weaknesses for studying different aspects of building ventilation, energy, and indoor air quality (IAQ). CFD modeling can be used for a microscopic view of a building or its components by solving Navier-Stokes equations to obtain detailed flow field information and pollutant concentration distributions within a space. Its strengths include the rigorous application of fundamental fluid mechanics and the detailed nature of the airflow, temperature, and contaminant concentration results. However, these results require significant time, both for the analyst to create a model and interpret the results and for the computer to solve the equations. This time cost typically limits CFD to applications involving single rooms and steady-state solutions.

In contrast, multizone airflow and pollutant transport modeling can yield a macroscopic view of a building by solving a network of mass balance equations to obtain airflows and average pollutant concentrations in different zones of a whole building. This entire process takes much less time, making whole-building modeling, including various mechanical systems, possible over time periods as long as a year. This method's limitations include far less-detailed results (e.g., no internal-room airflow details, a single contaminant concentration for each room), which poorly approximate some modeling scenarios (e.g., atria, stratified rooms).

Although modeling software is widely available, successful application of either indoor environmental modeling method is still challenging. A strong grasp of fundamental building physics and detailed knowledge of the building space being modeled are both necessary. (Also see Chapters 1, 3, 4, 6, 9, 11, 16, and 24 of this volume.) Successful modeling also starts with planning that considers the project's objectives, resources, and available information. When modeling existing buildings, taking measurements may significantly improve the modeling effort. Modeling is particularly useful when known and unknown elements are combined, such as an existing building under unusual circumstances (e.g., fire, release of an airborne hazard). However, even for hypothetical buildings (e.g., in the design stage), knowledge gained from a good modeling effort can be valuable to planning and design efforts.

The preparation of this chapter is assigned to TC 4.10, Indoor Environmental Modeling.

1. COMPUTATIONAL FLUID DYNAMICS

Computational fluid dynamic (CFD) modeling quantitatively predicts thermal/fluid physical phenomena in an indoor space. The conceptual model interprets a specific problem of the indoor environment through a mathematical form of the conservation law and situation-specific information (boundary conditions). The governing equations remain the same for all indoor environment applications of airflow and heat transfer, but boundary conditions change for each specific problem: for example, room layout may be different, or speed of the supply air may change. In general, a boundary condition defines the physical problem at specific positions. Often, physical phenomena are complicated by simultaneous heat flows (e.g., heat conduction through the building enclosure, heat gains from heated indoor objects, solar radiation through building fenestration), phase changes (e.g., condensation and evaporation of water), chemical reactions (e.g., combustion), and mechanical movements (e.g., fans, occupant movements).

CFD involves solving coupled partial differential equations, which must be worked simultaneously or successively. No analytical solutions are available for indoor environment modeling. Computer-based numerical procedures are the only means of generating complete solutions of these sets of equations.

CFD code is more than just a numerical procedure of solving governing equations; it can be used to solve fluid flow, heat transfer, chemical reactions, and even thermal stresses. Unless otherwise implemented, CFD does not solve acoustics and lighting, which are also important parameters in indoor environment analysis. Different CFD codes have different capabilities: a simple code may solve only laminar flow, whereas a complicated one can handle a far more complex (e.g., compressible) flow.

Mathematical and Numerical Background

Airflow in natural and built environments is predominantly turbulent, characterized by randomness, diffusivity, dissipation, and relatively large Reynolds numbers (Tennekes and Lumley 1972). Turbulence is not a fluid property, as are viscosity and thermal conductivity, but a phenomenon caused by flow motion. Research on turbulence began during the late nineteenth century (Reynolds 1895) and has been intensively pursued in academia and industry. For further information, see Corrsin's (1961) overview; Hinze's (1975) and Tennekes and Lumley's (1972) classic monographs; and Bernard and Wallace (2002), Mathieu and Scott (2000), and Pope (2000).

Indoor airflow, convective heat transfer, and species dispersion are controlled by the governing equations for mass, momentum in

Copyright © 2021, ASHRAE

each flow direction, energy (**Navier-Stokes equation**), and contaminant distribution. A common form is presented in Equation (1), relating the change in time of a variable at a location to the amount of variable flux (e.g., momentum, mass, thermal energy). Essentially, transient changes plus convection equals diffusion plus sources:

$$\frac{\partial}{\partial t}(\rho\phi) + \frac{\partial}{\partial x_j}(\rho U_j \phi) = \frac{\partial}{\partial x_j}\left(\Gamma_\phi \frac{\partial \phi}{\partial x_j}\right) + S_\phi \quad (1)$$

where

t = time, s
ρ = density, kg/m^3
ϕ = transport property (e.g., air velocity, temperature, species concentration) at any point
x_j = distance in j direction, m
U_j = velocity in j direction, m/s
Γ_ϕ = generalized diffusion coefficient or transport property of fluid flow
S_ϕ = source or sink

Local turbulence is expressed as a variable diffusion coefficient called the **turbulent viscosity**, often calculated from the equations for turbulent kinetic energy and its dissipation rate. The total description of flow, therefore, consists of eight differential equations, which are coupled and nonlinear. These equations contain first and second derivatives that express the convection, diffusion, and source of the variables. The equations can also be numerically solved [see the section on Large Eddy Simulation (LES)].

Direct solution of differential equations for the room's flow regime is not possible, but a numerical method can be applied. The differential equations are transformed into finite-volume equations formulated around each grid point, as shown in Figure 1. Convection and diffusion terms are developed for all six surfaces around the control volume, and the source term is formulated for the volume (see Figure 1B).

Assuming a room is typically divided into 90 × 90 × 90 cells, the eight differential equations are replaced by eight difference equations in each point, giving a total of 5.8×10^6 equations with the same number of unknown variables.

The numerical method typically involves 3000 iterations, which means that a total of 17×10^9 grid point calculations are made for the prediction of a flow field. This method obviously depends heavily on computers: the first predictions of room air movement were made in the 1970s, and have since increased dramatically in popularity, especially because computation cost has decreased by a factor of 10 every eight years. Baker et al. (1994), Chen and Jiang (1992), Nielsen (1975), and Williams et al. (1994a, 1994b) show early CFD predictions of flow in ventilated rooms, and Jones and Whittle (1992) discuss status and capabilities in the 1990s. Russell and Surendran (2000) review recent work on the subject.

Turbulent flow is a three-dimensional, random process with a wide spectrum of scales in time and space, initiated by flow instabilities at high Reynolds numbers; the energy involved dissipates in a cascading fashion (Mathieu and Scott 2000). Statistical analysis is used to quantify the phenomenon. At a given location and time, the instantaneous velocity u_i is

$$u_i = \overline{u}_i + u_i' \quad (2)$$

where $\overline{u}_i$ is the ensemble average of v for steady flow, and u_i' is fluctuation velocity. Through measurement, u_i' is obtained as the standard deviation of u_i. The turbulence intensity TI is

$$\text{TI} \equiv \frac{u_i}{\overline{u}_i} \times 100 \text{ in percent} \quad (3)$$

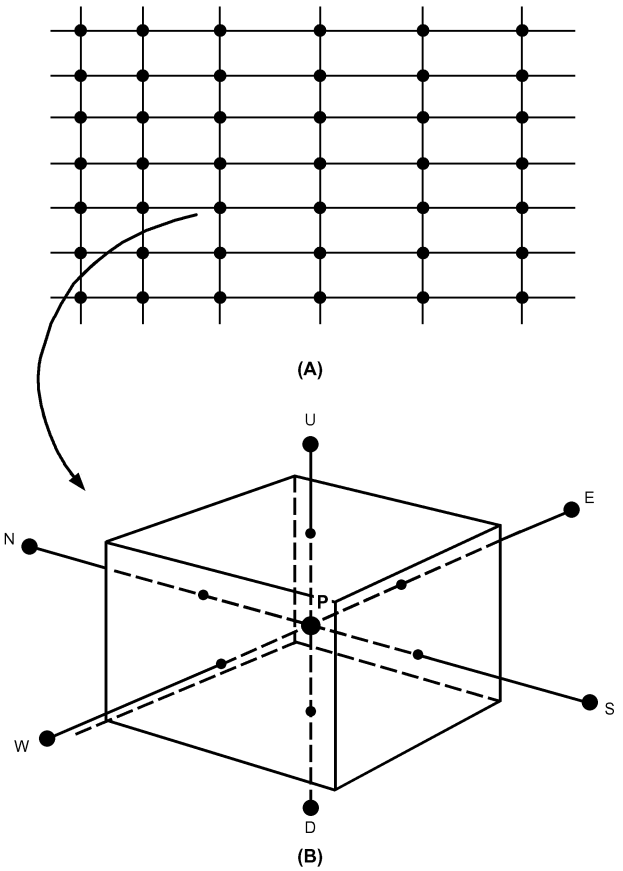

Fig. 1 (A) Grid Point Distribution and (B) Control Volume Around Grid Point P

The turbulent kinetic energy k per unit mass is

$$k = \frac{1}{2}\overline{u}_i'^2 = \frac{1}{2}(u_1'^2 + u_2'^2 + u_3'^2) \quad (4)$$

To quantify length and time, velocity correlations and higher moments of u_i are commonly used (Monin and Yaglom 1971). Those scales are essential to characterize turbulent flows and their energy transport mechanisms. With its turbulent kinetic energy extracted from the mean flow, large eddies cascade energy to smaller eddies. In the smallest eddies, viscous dissipation of the turbulent kinetic energy occurs. By equating the total amount of energy transfer to its dissipation rate ε, based on Kolmogorov's theory (Tennekes and Lumley 1972), a length scale η is defined as

$$\eta \equiv \left(\frac{\nu^3}{\varepsilon}\right)^{\frac{1}{4}} \quad (5)$$

where ν is the fluid's kinematic viscosity. The Kolmogorov length scale η is used to determine the smallest dissipative scale of a turbulent flow; it is important in determining the requirements of grid size [see the sections on Large Eddy Simulation (LES) and Direct Numerical Simulation (DNS)].

For an incompressible fluid, the governing equations of the turbulent flow motion are

$$\frac{\partial u_i}{\partial x_i} = 0 \quad (6)$$

Licensed for single user. © 2021 ASHRAE, Inc.

$$\rho\frac{\partial u_i}{\partial t}+\rho u_j\frac{\partial u_i}{\partial x_j}=-\frac{\partial P}{\partial x_i}+\frac{\partial \tau_{ij}}{\partial x_j} \tag{7}$$

where t is time, ρ is the fluid density, P is pressure, and τ_{ij} is the viscous stress tensor defined as

$$\tau_{ij}\equiv 2\mu s_{ij} \tag{8}$$

where μ is the dynamic viscosity and s_{ij} is the strain rate tensor, defined as

$$s_{ij}\equiv\frac{1}{2}\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right) \tag{9}$$

From Equations (6), (8), and (9), Equation (7) is rewritten as

$$\rho\frac{\partial u_i}{\partial t}+\rho\frac{\partial(u_iu_j)}{\partial x_j}=-\frac{\partial P}{\partial x_i}+\frac{\partial(2\mu s_{ij})}{\partial x_j} \tag{10}$$

Taking the ensemble average by using Equation (2), Equation (6) becomes

$$\frac{\partial \overline{u}_i}{\partial x_i}=0 \tag{11}$$

Considering Equation (2), Equation (10) becomes the **Reynolds-averaged Navier-Stokes (RANS) equation** (Wilcox 1998):

$$\rho\frac{\partial \overline{u}_i}{\partial t}+\rho\overline{u}_j\frac{\partial \overline{u}_i}{\partial x_j}=-\frac{\partial \overline{P}}{\partial x_i}+\frac{\partial(2\mu\overline{s}_{ij}-\rho\overline{u_i'u_j'})}{\partial x_j} \tag{12}$$

The right-hand term $-\rho\overline{u_i'u_j'}$ is called the **Reynolds stress tensor**. To compute the mean flow of turbulent fluid motion, this additional term causes the famous closure problem because of ensemble averaging, and must be calculated. Much turbulence research focuses on the closure problem by proposing various turbulence models.

Reynolds-Averaged Navier-Stokes (RANS) Approaches

The most intuitive approach to calculate Reynolds stresses is to adopt the mixing-length hypotheses originated by Prandtl. Many variants of the algebraic models and their applicability for various types of turbulent flows (e.g., free shear flows, wakes, jets) are collected and provided by Wilcox (1998).

Because of the importance of turbulent kinetic energy k in the turbulent energy budget, many researchers have developed models based on k and other derived turbulence quantities for calculating the Reynolds stresses. To solve the closure problem, the number of the additional equation(s) in turbulence models ranges from zero (Chen and Xu 1998) to seven [Reynolds stress model (RSM) for three-dimensional flows (Launder et al. 1975)]; all equations in these approaches are time-averaged. Two-equation variants of the k-ε model (where ε is the dissipation rate of turbulent kinetic energy) are popular in industrial applications, mostly for simulating steady mean flows and scalar species transport (Chen et al. 1990; Horstman 1988; Spalart 2000). A widely used method is predicting eddy viscosity μ_t from a two-equation k-ε turbulence model, as in Launder and Spalding (1974). Nielsen (1998) discusses modifications for room airflow. The k-ε turbulence model is only valid for fully developed turbulent flow.

Flow in a room will not always be at a high Reynolds number (i.e., fully developed everywhere in the room), but good predictions are generally obtained in areas with a certain velocity level. Low-turbulence effects can be predicted near wall regions with, for example, a Launder-Sharma (1974) low-Reynolds-number model.

More elaborate models, such as the Reynolds stress model (RSM), can also predict turbulence. This model closes the equation system with additional transport equations for Reynolds stresses [see Launder (1989)]; it is superior to the standard k-ε model because anisotropic effects of turbulence are taken into account. For example, the wall-reflection terms damp turbulent fluctuations perpendicular to the wall and convert energy to fluctuations parallel to the wall. This effect may be important for predicting a three-dimensional wall jet flow (Schälin and Nielsen 2004).

In general, RSM gives better results than the standard k-ε model for mean flow prediction, but improvements are not always significant, especially for the velocity fluctuations (Chen 1996; Kato et al. 1994). Murakami et al. (1994) compared the k-ε model, algebraic model (simplified RSM), and RSM in predicting room air movement induced by a horizontal nonisothermal jet. RSM's prediction of mean velocity and temperature profiles in the jet showed slightly better agreement with experiments than the k-ε model's prediction.

Large Eddy Simulation (LES)

For intrinsically transient flow fields, time-dependent RANS simulations often fail to resolve the flow field temporally. Large eddy simulation (LES) directly calculates the time-dependent large eddy motion while resolving the more universally small-scale motion using subgrid scale (SGS) modeling. LES has progressed rapidly since its inception four decades ago (Ferziger 1977; Smagorinsky 1963; Spalart 2000), when it was mainly a research tool that required enormous computing resources; modern computers can now implement LES for relatively simple geometries in building airflow applications (Emmerich and McGrattan 1998; Lin et al. 2001). For an excellent introduction to this promising CFD technique, see Ferziger (1977).

Filtering equations differentiate mathematically between large and small eddies. For example,

$$\bar{f}(r)=\int_{R^3}f(r')G_\Delta(r,r')dr' \tag{13}$$

where $G_\Delta(r,r')$ is a filter function with a filter with length scale Δ. $G_\Delta(r,r')$ integrates to 1 and decays to 0 for scales smaller than Δ (Chester et al. 2001). To resolve the SGS stresses, an analog to the RANS approach for the Reynolds stress is implemented as

$$u_i=<u_i>+<u_i'> \tag{14}$$

where $<u_i>$ is the filtered average defined by Equation (13) and $<u_i'>$ is the subgrid scale velocity, which is calculated through subgrid modeling. Filtering Equation (6) and (7) gives

$$\frac{\partial <u_i>}{\partial x_i}=0 \tag{15}$$

$$\rho\frac{\partial <u_i>}{\partial t}+\rho\frac{\partial <u_iu_j>}{\partial x_j}=-\frac{\partial <p>}{\partial x_i}+\frac{\partial <2\mu s_{ij}>}{\partial x_j} \tag{16}$$

Based on Equation (14), the $<u_iu_j>$ term in Equation (16) becomes,

$$\begin{aligned}<u_iu_j>=&<<u_i><u_j>>+<<u_i'><u_j>>\\&+<<u_i><u_j'>>+<<u_i'><u_j'>>\end{aligned} \tag{17}$$

The last three terms that contain the subgrid velocity are therefore the subject of modeling (Ferziger 1977). Breuer (1998) and Spalart (2000) describe some of the many other subgrid models and their performance. The latest developments of LES and its related

Licensed for single user. © 2021 ASHRAE, Inc.

techniques, such as the detached eddy simulation (DES), are described in detail by Spalart (2000).

Direction Numerical Simulation (DNS)

Direct numerical simulation (DNS) is used to study turbulent flow. This method is very accurate (sometimes better than experiments), and is used to benchmark performance of other CFD techniques. Because of its stringent requirements on grid, especially in the normal direction within the boundary layer (Grötzbach 1983), DNS is used to study spatially and temporally confined flows with simple geometry (Spalart 2000). Notwithstanding these limits, DNS also has been used to explore more complicated geometry, such as flow over a wavy wall (Cherukat et al. 1998), and flow mechanisms, such as multiphase flow (Ling et al. 1998) and droplet evaporation (Mashayek 1998).

1.1 MESHING FOR COMPUTATIONAL FLUID DYNAMICS

The first step in conducting a CFD analysis for a fluid region of interest is to divide the region into a large number of smaller regions called **cells**. The collection of cells that makes up the domain of interest is typically called the **mesh** or **grid**, and the process of dividing up the domain is called **meshing**, **gridding**, **grid generation**, or **discretization** of the computational domain.

Meshes can be structured or unstructured, depending on the connectivity of the cells in the mesh to one another. Individual cell shape varies, and each shape has advantages and disadvantages. These shapes range from triangles and quadrilaterals for two-dimensional (2D) geometry, to tetrahedrals (four-sided triangular-based shapes) and hexahedrons (typically six-sided boxes) for three-dimensional (3D) geometry. Wedges (a triangle swept into a three-dimensional shape) and rectangular-based pyramids can also be used to transition between the triangular sides of the tetrahedrals and quadrilateral sides of the hexahedrons.

Structured Grids

Structured grids have consistent geometrical regularity, wherein families of grid lines (in one direction) do not cross each other. Figure 2 shows examples of structured grids. These grids can be further subclassified as orthogonal and nonorthogonal.

Orthogonal structured grids, the simplest scheme, are based on Cartesian/polar-cylindrical coordinate systems. A curved or sloped boundary in the CFD domain is typically approximated by stepwise boundary. Figure 2A shows a meshed 2D domain for flow through a 90° elbow using a Cartesian orthogonal coordinate system. Cells outside the elbow are blocked from CFD analysis or turned into cells that do not participate in the flow field. The stairstep approach to representing the curved surface can lead to numerical errors at curved walls. Finer grids are needed to more accurately represent the curved/sloped boundary. The effect of reducing local grid size in one region (grid refinement) may propagate to other sections of the domain and result in an increase in the number of model cells. This, together with the blocked cells outside the flow domain, creates a burden on computing resources. The stepwise approximation of the boundary may also result in errors that negatively affect the CFD solution.

Modeling curved/sloped surfaces is possible by using the geometrical flexibility of the **nonorthogonal** grid, also known as **body-fitted** or **boundary-fitted grid**. An example of a 2D body-fitted nonorthogonal structured grid for a 90° elbow is shown in Figure 2B. Using the body-fitting method, geometric details are accurately represented without using stepwise approximation. An orthogonal grid can be structured (i.e., a single block, as in Figure 2), block-structured, or overlapping-structured.

A **block-structured** grid consists of a group of meshed regions (blocks) that collectively form the entire region of interest. This is typically referred to as a **multiblock domain**. The blocks may have a fine grid at the region of interest, to provide more details for flow field analysis, and a coarser grid away from the region of interest. Figure 3 shows block-structured grid for 2D flow through a 90° elbow connected to a rectangular duct. The grid is fine close to the solid surfaces, and is refined at point A, where flow separation is expected. This grid refinement is propagated through blocks 2 and 3. Interblock interfaces could have matching grids, as between blocks 1 and 2, or a nonmatching interface, as between blocks 2 and 3. The nonmatching interface is used to transfer from coarse to finer grid or vice versa. Numerical inaccuracies can occur where blocks are joined together with nonmatching mesh lines. The relative difference in mesh size on either side of the interface is important. Also, there is additional computational overhead associated with managing the nonconformal interface.

At the interface of the block-structured grid, the ratio of cell size change (i.e., large to small cells) between two blocks is recommended to be no more than two (Ferziger and Peric 1997), because transporting field variables from a fine to a coarse mesh or vice versa allows inaccuracies to enter the solution. If flow in a domain travels from a group of four cells to a single cell, the flow detail represented by the four cells is lost. In some cases, this rule can be bent, but this is best done by an experienced CFD modeler.

Structured grids simplify programming for the CFD code developer and provide regular structure for the matrix of algebraic equations. However, they may not adequately describe complex geometries, and it can be difficult to control grid distribution in the region of interest without propagating through the whole analyzed domain.

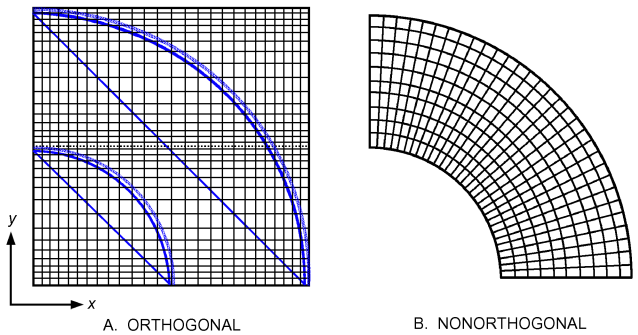

Fig. 2 Two-Dimensional CFD Structured Grid Model for Flow Through 90° Elbow

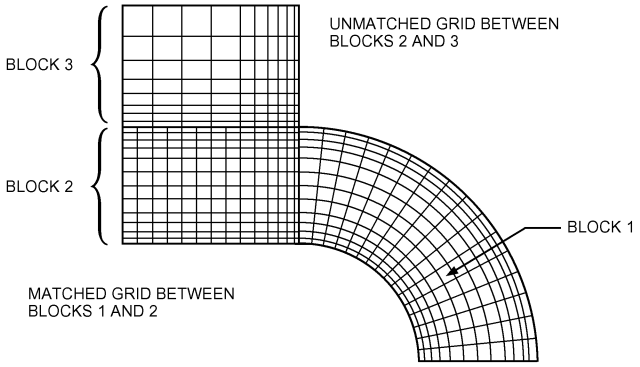

Fig. 3 Block-Structured Grid for Two-Dimensional Flow Simulation Through 90° Elbow Connected to Rectangular Duct

Licensed for single user. © 2021 ASHRAE, Inc.

These structured grid types are mainly associated with finite-difference methods. The examples in Figures 2 and 3 are called the **physical planes**. Finite-difference methods require a uniform rectangular grid called the **computational plane**. The governing equations must be transformed to give one-to-one correspondences between the physical and computational planes. After analysis of the computational plane, the results are transferred back to the corresponding point on the physical plane. Using data transformation increases the programming efforts and computing costs for CFD. Anderson (1995) has more information on transformation methods.

Unstructured Grids

Unstructured grids (Figure 4) are flexible: they can represent complex geometry boundaries, and can be easily refined in the region of interest without propagating to the rest of the domain. Elements of different shapes can be used in the domain. Either matching or nonmatching nodes can be used between neighboring elements. Figure 4A is an unstructured grid using tetrahedral elements, whereas Figure 4B uses hexahedral elements; note that both have a meshing zone near the pipe wall to resolve the boundary layer. Unlike structured grids, the matrix of algebraic equation does not have a regular diagonal structure and has a slower solver than a structured grid solver (Ferzinger and Peric 1997).

Unstructured grids are mostly used for finite-element and finite-volume methods. No transformations are required for finite-volume methods, and analysis can be performed directly on the physical plane of the unstructured grid.

Grid Quality

Grid quality measures include the shape of the individual cells, the size of the cell relative to flow field features of interest, and the jump in grid size from one block to the next.

Cell quality is important. Values for variables stored at centers of cells must be interpolated to the face of the cell, which allows calculation of fluxes at faces of control volumes. A poor-quality mesh gives less accurate interpolations and can affect the quality of the simulation result by the introducing numerical inaccuracies. Mildly poor grids can increase convergence times; in extreme cases, local poor cell quality can result in overall flow field inaccuracies or cause the simulation to diverge and not reach a solution at all.

The examples in Figures 2 to 4 show clean, nonskewed cell shapes: the triangles do not lean over and the quadrilaterals have corners that do not vary significantly from 90°. In many practical meshes, the individual cells become distorted from these ideal shapes (e.g., because four-sided shapes may not fit well into wedge-shaped corners). The amount of distortion is typically referred to as **skewness**. Different CFD codes allow different levels of skewness, and the solver's overall sensitivity to skewness may be affected by the method of numerical discretization.

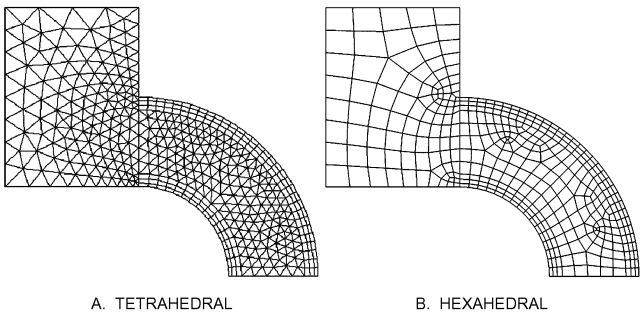

Fig. 4 Unstructured Grid for Two-Dimensional Meshing Scheme Flow Simulation Through 90° Elbow Connected to Rectangular Duct

Grid cell size may be partially determined by the level of geometric detail needed. Cells need to be small enough to resolve the smallest geometric features of the domain. If cell size is too large, any curved elements cannot be represented by a series of straight lines.

In addition, a CFD solution's ability to resolve flow field features is limited by the grid resolution. If a grid has cell sizes of 10 mm, then flow field features smaller than 20 mm cannot be solved. Therefore, sharp gradients of flow field variables necessitate a finer mesh. The additional cells in the finer mesh are required to resolve the rapid change in the flow field variable. Additionally, fine grid resolution at walls is important for methods that use the law of the wall (see the Wall/Surface Boundary Conditions section), because fluxes and shear at the wall require accurate calculations of gradients.

Many CFD codes can start with a coarse mesh and add cells as necessary in particular regions, which can save computational time in the set-up and test simulation phases.

When generating a mesh, it is important to determine whether the mesh itself will affect the simulation and generate erroneous results. Figure 5 shows three circles with different meshing schemes. Figure 5A shows a grid on the circle that has a pincushion-like look; this mesh distorts the flow field in the "corners," because the four corner cells have two sides on the perimeter of the circle, whereas the rest of the cells around the circumference have only one. If this mesh is used to simulate flow down a pipe, flow velocity in the corner cells is adversely affected by the additional friction that these cells experience. Figure 5B shows the same geometry, but with a structured mesh created by placing a square in the center of the circle and drawing rays diagonally out from the corners. These rays and the circle's perimeter define other meshing blocks. If cut halfway through the horizontal or vertical centerline, the mesh can be stretched out into a rectangle. Finally, Figure 5C shows an unstructured mesh over the same geometry. The meshes in Figures 5B and 5C influence results less significantly than that in Figure 5A.

Immersed Boundary Grid Generation

The preceding discussion assumes that a 2D or 3D computer model already exists for the geometry, architecture, or region of interest, and that the geometry can be imported into a gridding software package. The grid is then overlaid onto that geometry.

In immersed boundary grid generation, a model is not required to exist a priori. This simplifies gridding and geometry generation in one step: the orthogonal structured grid is created within a block and then the geometry (represented by blanked-out sections of cells within the meshed block) is overlaid (see Figure 1A). Groups of meshed blocks with overlaid architecture can be assembled to generate more complicated computational domains.

Although this technique can yield high-quality meshes for simple geometrical features (blocked representation), more sophisticated grid-generation techniques may be needed to grid complicated domains.

Grid Independence

The level of grid independence from the flow field solution is important to determine in advance. It may be sufficient to demonstrate

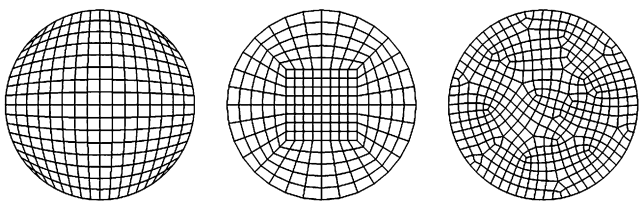

Fig. 5 Circle Meshing

Licensed for single user. © 2021 ASHRAE, Inc.

that grids of similar resolution applied to similar problems give sufficiently low levels of uncertainty.

Grid independence can be achieved experimentally by using successive grid refinements in areas with sharp gradients or cell skewness. This allows solutions obtained with coarser and finer grids to be compared. If results of two successive trials are comparable, then both models are grid-independent. In some cases, experienced CFD practitioners may be able to identify a sufficiently grid-independent solution without trials, but new CFD users should not assume a solution is grid independent: different levels of grid can yield results different enough to make conclusions drawn from the flow field unreliable.

1.2 BOUNDARY CONDITIONS FOR COMPUTATIONAL FLUID DYNAMICS

Boundary conditions are integral to CFD modeling's ability to solve the general Navier-Stokes equations for a particular problem in an indoor environment. Boundary conditions specify physical and/or chemical characteristics at the model's perimeters. These characteristics could be constant throughout the analysis or time-dependent in transient analyses. This section discusses applying boundary conditions for CFD modeling of subsonic fluid flow.

Excluding free surface flow, most boundary conditions can be classified as either **Dirichlet** (variable values specified at the boundary node) or **Neumann** (variable derivatives are required at the boundary, and the boundary condition must be discretized to provide the required equation). Free surface flow requires moving boundary conditions, such as **kinematic** and **dynamic**.

Every model has walls, and most have at least one inlet and one outlet boundary. Some cases of natural convection heat transfer (e.g., CFD modeling of an enclosure with heated and cooled sides, modeling of convection from an object such as cylinder in a large fluid medium) may not require an inlet or outlet in the model. Typical boundary condition types for HVAC applications are inlets, outlets, walls or surfaces, symmetry surfaces, and fixed sources or sinks.

Inlet Boundary Conditions

Special attention must be paid to inlet boundary conditions, because supply diffusers are usually dominant sources of momentum that create airflow patterns responsible for temperature and concentration distributions.

Inlet boundary conditions may be velocity, pressure, or mass flow. When details of flow distribution are unknown, a constant-pressure boundary or constant flow rate can be specified. The pressure inlet boundary requires specifying static pressure for incompressible flow. Stagnation pressure and stagnation temperature should be specified at the pressure boundary for compressible flow. In both conditions, velocity components at the boundary are obtained by extrapolation.

The mass flow inlet condition requires specifying the mass flow rate and temperature for incompressible flow at the boundary. Velocities and pressure are calculated by extrapolation at inlet boundaries.

Experimentally measured values of turbulence quantities at the inlet boundary are also required for accurate CFD simulation for turbulent flow. For the k-ε turbulence model, turbulent kinetic energy k and turbulent dissipation rate ε are required. When these values are not available from experimental data, they can be estimated from the following equations:

$$k = \frac{3}{2}(U_{ref}\,\mathrm{TI})^2 \tag{18}$$

$$\varepsilon = C_\mu^{3/4} \times \frac{k^{3/2}}{l} \tag{19}$$

$$l = 0.07L \tag{20}$$

where U_{ref} is the mean stream velocity, TI is turbulence intensity, l is the turbulence length scale, C_μ is the k-ε turbulence model constant ($C_\mu = 0.0845$), and L is the characteristic length of the inlet (for a duct, L is the equivalent radius).

For indoor environmental modeling, the inlet boundary is especially important because of the potentially complex geometry of supply diffusers designed to produce particular performance characteristics. Detailed diffuser modeling is possible for limited regions near the diffuser, but is not very practical in room-flow simulations: including the small geometric details of the diffuser in the room model results in a mesh with so many cells that current computation resources cannot efficiently find a solution. Therefore, most room airflow simulations should use simplified diffuser modeling that replicates diffuser performance without explicitly modeling the fine geometric details of the diffuser.

Other simplifications are possible. The most obvious method is replacing the actual diffuser with a less-complicated diffuser geometry, such as a slot opening, that supplies the same flow momentum and airflow rate to the space as the actual diffuser does (Nielsen 1992; Srebric and Chen 2002). Simplified methods are classified as jet momentum modeling either (1) at air supply devices or (2) in front of air supply devices (Fan 1995). Modeling at the supply device has several variations, including the slot and momentum models; variations of modeling in front of the diffuser include prescribed velocity, box, and diffuser specification (Srebric and Chen 2001, 2002). The most widely used methods are the momentum, box, and prescribed velocity methods.

The **momentum** method decouples the momentum and mass boundary conditions for the diffuser (Chen and Moser 1991). The diffuser is represented with an opening that has the same gross area, mass flux, and momentum flux as a real diffuser. This model allows source terms in the conservation equations to be specified over the real diffuser area. Air supply velocity for the momentum source is calculated from the mass flow rate m and the diffuser effective area A_0:

$$U_0 = \frac{m}{\rho A_0} \tag{21}$$

The momentum method is very simple, but might not work well for certain types of diffusers (Srebric and Chen 2002).

The **box** method is based on the wall jet flow generated close to the diffuser (Nielsen 1992; Srebric and Chen 2002). Figure 6 shows the location of boundary conditions around the diffuser. Details of flow immediately around the supply opening are ignored, and the supplied jet is described by values along surfaces a and b. There are two advantages of this method compared to the detailed diffuser simulations: (1) the box method does not require as fine a grid as fully numerical prediction of the wall jet development; and (2) two-dimensional predictions can be made for three-dimensional supply openings, provided that the jets develop into a two-dimensional wall

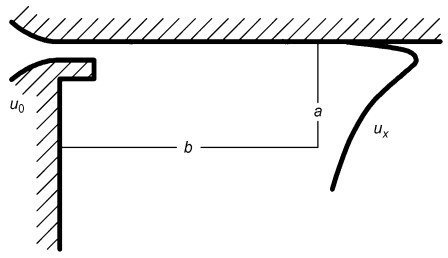

Fig. 6 Boundary Condition Locations Around Diffuser Used in Box Method

Licensed for single user. © 2021 ASHRAE, Inc.

jet or free jet at a certain distance from the openings. Data for velocity distribution in a wall (or free) jet generated by different commercial diffusers can be obtained from diffuser catalogues or design guide books, Chapter 20, and textbooks [e.g., Awbi (1991), Etheridge and Sandberg (1996), and Rajaratnam (1976)].

The **prescribed velocity** method has also been used in numerical prediction of room air movement. Figure 7 shows the method's details. Inlet profiles are given as boundary conditions of a simplified slot diffuser, represented by only a few grid points. All variables except velocities u and w are predicted in a volume close to the diffuser (x_a, y_b) as well as in the rest of the room. Velocities u and w are prescribed in the volume in front of the diffuser as the fixed analytical values obtained for a wall jet from the diffuser, or they are given as measured values in front of the diffuser (Gosman et al. 1980; Nielsen 1992).

For a more detailed description of simplified methods and their applicability to common supply diffusers, see Chen and Srebric (2000). Figure 8 shows how real diffusers can be simplified by the momentum method and box method in CFD simulations (Srebric 2000).

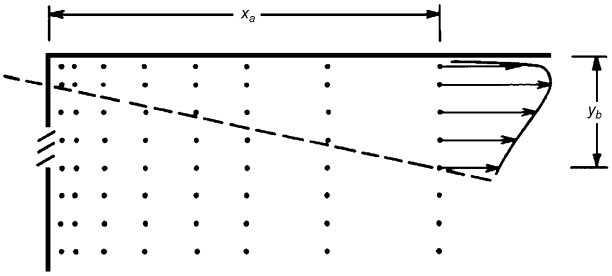

Fig. 7 Prescribed Velocity Field Near Supply Opening

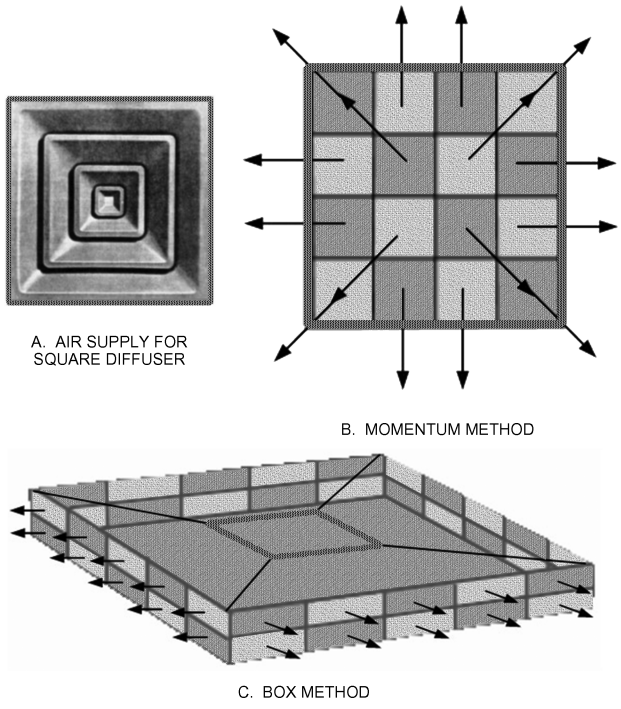

Fig. 8 Simplified Boundary Conditions for Supply Diffuser Modeling for Square Diffuser

Outlet Boundary Conditions

A mass flow rate or constant pressure can be specified for an outlet boundary condition. The outlet flow rate or pressure boundary is extrapolated to determine the boundary velocity, which needs to be corrected during calculations to satisfy mass conservation in the analyzed domain. Some commercial CFD codes require turbulence values at outlet boundary conditions. These values are used when reversed flow occurs at the outlet pressure boundary.

Wall/Surface Boundary Conditions

Wall boundary conditions represent the wet, solid perimeter of the CFD model. All velocity components are set equal to wall velocity for no-slip wall conditions, and to zero for a stationary wall. This is an example of a Dirichlet boundary condition. Wall roughness for both types of flow regimes (laminar and turbulent) should be specified. At the wall, both regimes have laminar flow. For turbulent flow, the wall turbulent boundary layer consists of three sublayers as presented in Figure 9 (Wilcox 1998): a thin, viscous sublayer followed by the log-law layer and the defect layer. Turbulent flow modeling requires very fine mesh inside the boundary layer. This requires extensive computational hardware, which is very costly, but the resource requirements can be reduced by using empirical wall functions in the near wall region instead of directly applying the k-ε turbulence model with a very fine mesh.

Turbulent flow near a wall can be categorized as **laminar** (viscous sublayer) or **turbulent** (log-law layer), depending on the dimensionless distance Y^+ from the wall, defined as

$$Y^+ = \frac{\Delta Y_p}{\nu}\sqrt{\frac{\tau_w}{\rho}} \tag{22}$$

where ΔY_p is the distance from the wall to the center of the first cell, τ_w is wall shear stress, ρ is fluid density, and ν is the fluid kinematic viscosity.

The viscous sublayer is very thin ($Y^+ < 5$), and is typically smaller than the first cell ($2\Delta Y_p$). For the viscous sublayer, as shown in Figure 9,

$$u^+ = Y^+ \tag{23}$$

where u^+ is the dimensionless mean velocity ($u^+ = U_P/u_t$, $u_t = \sqrt{\tau_w/\rho}$, and U_P is the is the velocity parallel to the wall at ΔY_p).

In practical terms, most important layer is the turbulent log-law sublayer, which is characterized by the following dimensionless velocity profile:

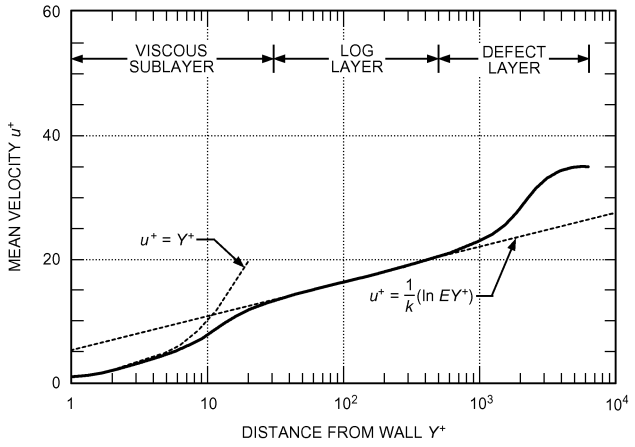

Fig. 9 Typical Velocity Distribution in Near-Wall Region

Licensed for single user. © 2021 ASHRAE, Inc.

$$u^+ = \frac{1}{\kappa}(\ln EY^+) \tag{24}$$

where κ is Von Karman's constant (κ = 0.41), and E is a constant depending on the wall roughness (E = 9.8 for hydraulically smooth walls).

The size of the log-law layer is typically $30 < Y^+ < 500$ (Versteeg and Malalasekera 1995). The turbulent kinetic energy k and turbulent dissipation rate ε use the following functions in the log-law layer:

$$k = \frac{u_\tau^2}{\sqrt{C_\mu}} \quad \text{and} \quad \varepsilon = \frac{u_\tau^3}{\kappa y} \tag{25}$$

where C_μ is the k-ε turbulence model constant.

Overall, wall functions are of great practical importance because they allow significant savings of computational time. However, assumptions used to derive the wall functions [i.e., Prandtl mixing hypothesis, Boussinesq eddy viscosity assumption, fully developed flow, and no pressure gradients or other momentum sources (constant shear stresses)] restrict their application to a certain class of flows. For indoor airflow applications, these assumptions are acceptable, and wall functions are widely used. However, predicted heat transfer in the near-wall region tends to be incorrect, depending on the control volume size at the wall (Yuan et al. 1994). Heat transfer calculation can be improved with more accurate temperature profile equations or use of prescribed empirical values for the convective heat transfer coefficient h.

Surface temperature and heat transfer are often complicated variables of time and position. However, many CFD simulations use steady-state boundary conditions for a typical or design day. Boundary conditions for surface temperature and heat transfer are illustrated in Figure 10, showing how surface temperature T_s depends on heat transfer to and from the surroundings, on radiation to and from the surfaces in the room, and on the air temperature close to the surface.

Boundary conditions for temperature or energy flux can be found from measurements, manual energy calculations, or a **building energy performance simulation (BEPS)** program. BEPS predicts both energy flow in the building structure and radiation plus detailed dynamic energy flow and consumption of the whole building during a period of time (Figure 11). There are different ways to exchange heat transfer information between BEPS and CFD programs (Zhai et al. 2002); the best method is to transfer surface temperatures from BEPS to CFD, and convective heat transfer coefficients and air temperature from CFD to BEPS, to achieve a unique solution (Zhai and Chen 2003).

Dynamic simulations can be structured in different ways. A BEPS program can be connected to a separate CFD program, which predicts energy flow in selected situations. A CFD program can also be extended to find a combined solution of radiation, conduction, and thermal storage parallel to solving the flow field; this is often called a conjugate heat transfer model. Another possibility is to use additional CFD code in selected rooms as an extension of a large BEPS program. Examples of conjugate heat transfer and combined models are available in Beausoleil-Morrison (2000), Chen (1988), Kato et al. (1995), Moser et al. (1995), Nielsen and Tryggvason (1998), Srebric (2000), and Zhai and Chen (2003).

The simplest way to account for heat transfer at CFD boundaries is to prescribe wall temperatures obtained from on-site measurements. Using a turbulence model without wall functions is also recommended when heat and mass flows from surfaces are the important parameters. Predictions of actual flow at surfaces are more accurate than analytical values found from wall functions.

Symmetry Surface Boundary Conditions

For a model with symmetrical flow in at least one plane, the symmetry boundary condition represents no flow across the symmetry plane, and all scalar fluxes are set to zero.

Select symmetry boundary conditions cautiously. Although the geometry of the model has symmetry, fluid flow might not be

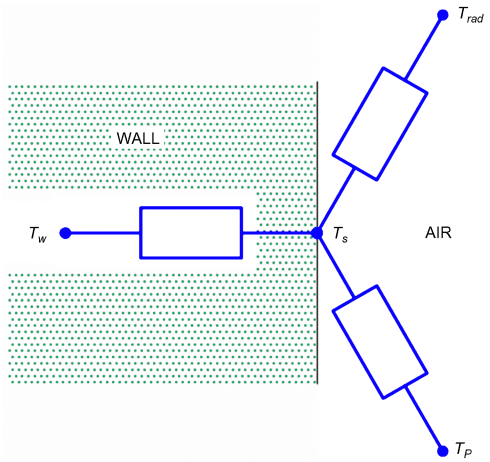

Fig. 10 Wall Surface Temperature T_s, Influenced by Conduction T_w, Radiation T_{rad}, and Local Air Temperature T_P

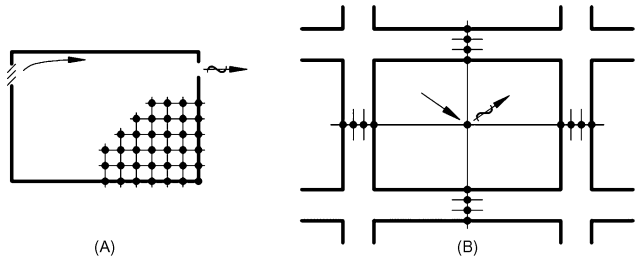

Fig. 11 Combination CFD and BEPS
The CFD program predicts flow in room based on heat flux calculated by BEPS program.

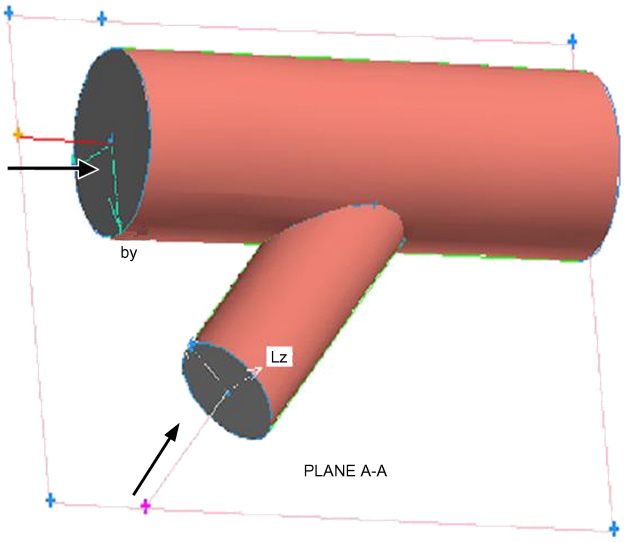

Fig. 12 Duct with Symmetry Geometry

Licensed for single user. © 2021 ASHRAE, Inc.

symmetrical at the geometry symmetry plane. In Figure 12, the geometry is symmetrical at plane A-A, but the flow is asymmetrical because of flow instability at the merged flow region.

Zhang et al. (2000) studied the symmetry pattern for a an 8.5 by 5 by 3 m room, with air supplied through a slot at the ceiling and along the 5 m long side. Return air exited through a slot at the floor along the same side wall as the inlet air. Velocity on one side of the symmetry plane was up to two times higher than on the other side, at the symmetrical location.

Fixed Sources and Sinks

Fixed sources are boundary conditions specified as fixed values of the calculated parameter or as mass/momentum/heat/contaminant fluxes. Examples include heat flux from a wall to simulate solar radiation, total heat flow in the occupied zone to simulate heat dissipation from occupants, momentum source from an operating fan, and species generation rate from contaminant sources. These sources could be placed anywhere in the CFD calculation domain, and can vary with time. Fixed-value sources/sinks usually use the wall functions if the source/sink is given as a fixed value, whereas fixed-flux sources/sinks do not use wall functions. These boundary conditions could also be associated with blockages in the flow domain (e.g., furniture, occupants, or other flow obstacles).

Modeling Considerations

Pressure boundary conditions are used when there is not enough information to specify the flow distribution, and the boundary pressure is known or assumed. Pressure boundaries are mostly used for buoyancy-driven flow and external flow applications. In inlet/outlet pressure boundary conditions, the stagnation pressure, temperature, concentration, and turbulence quantities k and ε are required. For external flow away from the wall, the free-stream k and ε can be set to zero. A pressure boundary velocity cannot be specified, but must be determined by the CFD code from interior conditions relative to the pressure boundary condition (inflow or outflow condition is possible).

When using different boundary conditions, be aware that most boundary conditions are just approximations of real physical phenomena. It is the user's responsibility to evaluate adequacy and influence of different boundary conditions on the accuracy of CFD simulation solutions.

1.3 CFD MODELING APPROACHES

Some steps are common to developing all types of CFD models and can increase the likelihood of getting a reasonable result with appropriate computing time.

Planning

Planning a CFD simulation is perhaps the most important step. During this phase, a clear understanding of what is being investigated is important. If the simulation is about thermal comfort in a room, some details about unoccupied space regions may be simplified: there may be little point in determining the thermal comfort in an unoccupied zone. If the purpose is to gain insight into a flow field, then some effort to estimate flow patterns helps during early modeling decisions and later evaluation of results.

During planning, a decision of whether to conduct a steady-state or transient simulation must be made. Transient simulations present time-accurate results, such as filling a tank, whereas steady-state simulations represent conditions after the flow field has been flowing long enough to reach equilibrium. It is important to recognize that some flows are inherently unsteady. The effect of choosing a steady-state solver to model unsteady flow should be considered during this process.

The physics to be examined should also be determined. Turbulence, heat transfer, species transport, and radiation phenomena can be evaluated during CFD modeling.

The final stage of planning is to determine how to represent the boundary conditions and flow physics. Diffusers, thermal sources leading to plumes, and contaminant sources are all important flow details that need to be appropriately represented.

Dimensional Accuracy and Faithfulness to Details

Highly detailed representation of architecture in a CFD model can significantly add to grid and computational costs. Often, high detail is not required. For instance, including doorknobs on a door will not likely change the simulation results greatly except immediately around the doorknob itself. However, if the room is negatively pressurized, significant flow through a crack beneath the door can cause a jet to propagate into the room, so accurately representing effects of flow through the crack is important. If the simulation is intended to assess thermal comfort in a laboratory with fume hoods, then the fume hood sash details may not be very important. However, if the purpose of the simulation is to evaluate fume hood capture performance, the sash opening detail can be important.

For complicated models, it can be helpful to evaluate and include the potential modifications for subsequent simulations before completing the geometry. This allows the simulation to be modified without breaking the grid and geometry, which can be the most time-consuming step of simulation. Preparing the grid for future simulations may reduce overall costs for later simulations.

CFD Simulation Steps

The basic mechanical steps in CFD simulation are as follows:

1. Create the geometry (a 3D model of the simulation environment)
2. Generate the grid
3. Define surfaces and volumes and implement boundary conditions
4. Execute the simulation
5. Evaluate the simulation and conduct quality checks to determine whether CFD simulation is complete; refine the grid, change discretization, and continue to solve
6. Postprocess/analyze the simulation to extract desired information
7. Modify the simulation and redo as required

During planning, a large set of physical phenomena (e.g., turbulence, heat transfer, radiation, species transport, combustion) may need to be included within the simulation(s). When executing the simulation itself, starting with a minimal set of physics and then increasing the level of complexity has advantages. For example, for flow in a room with a large convective and radiant heat source from which a contaminant is escaping (e.g., an industrial furnace), (1) solve the fluid velocity field with turbulence, (2) calculate energy to get a temperature distribution, (3) add radiation to redistribute some thermal energy, and (4) track the contaminant by adding species transport equations to the simulation.

This stepped approach allows the modeler to build on previous flow field solutions and ensure that each new set of physics is starting from a reasonable estimate of the flow field. It has particular advantages for complicated models or increasing the probability of success for new users.

1.4 VERIFICATION, VALIDATION, AND REPORTING RESULTS

It is important to document and assess the credibility of CFD simulations through verification, validation, and reporting of results. The American Institute of Aeronautics and Astronautics (AIAA 1998) defines *verification* as "the process of determining that a (physical/mathematical) model implementation accurately represents the

Licensed for single user. © 2021 ASHRAE, Inc.

developer's conceptual description of the model and the solution on the model," and *validation* as "the process of determining the degree to which a (CFD) model is an accurate representation of the real world from the perspective of the intended uses of the model."

Verification ensures that a CFD code can accurately and correctly solve the equations used in the conceptual model; it does not imply that the computational results represent physical reality. Generally, verification is done during code development. Because very few HVAC engineers who do indoor environment analysis develop CFD codes, this section focuses mostly on code applications, not development. In addition, time and money available for simulation are usually limited, which requires that verification and validation be realistically achievable. Therefore, this section refines the definitions of verification, validation, and reporting of results:

- **Verification** identifies relevant physical phenomena for analysis and provides instructions on how to assess whether a particular CFD code can account for those physical phenomena.
- **Validation** provides instructions on how to demonstrate the coupled ability of a user and a CFD code to accurately conduct representative indoor environmental simulations with available experimental data.
- **Reporting** results provides instructions on how to summarize results so that others can make informed assessments of the value and quality of the CFD work.

Therefore, verification should represent physical realities, although the cases can be very simple, containing only one (or a few) flow and heat transfer features of the complete system. The validation cases should be close to reality and include the flow and heat transfer characteristics that need to be analyzed, although approximations may be used in the validation.

This section describes a procedure developed by Chen and Srebric (2002) for verification, validation, and reporting of CFD results, but its intent is not to develop standards. The extent of CFD's capability in modeling has not yet been developed to the point where standards can be written (AIAA 1998).

Verification

The basic physical phenomena of the indoor environment are airflow, heat transfer (conduction, convection, and radiation), mass transfer (species concentrations and solid and liquid particles), and chemical reactions (combustion). Therefore, the first step of verification is to identify benchmark cases with one or more flow and heat transfer features of those basic phenomena.

In some indoor regions, airflow can be laminar or weakly turbulent. The overall flow features are often considered as turbulent. Most indoor airflows are turbulent because of the high Rayleigh number Ra, and sometimes high Reynolds number Re, defined as

$$\mathrm{Ra} = \beta g\,\Delta T L^2/\nu k \tag{26}$$

$$\mathrm{Re} = UL/\nu \tag{27}$$

In most rooms, Ra ranges from 10^9 to 10^{12} and Re from 10^4 to 10^7 if room height is used as the characteristic length L. Experiments have found that turbulence occurs when $\mathrm{Ra} > 10^9$ and/or $\mathrm{Re} > 10^4$.

Turbulence modeling approximations, which require more complex numerical schemes so that a converged solution can be achieved, must be made for CFD to solve the flow fields.

The ability of a CFD code to simulate airflow in an indoor environment and the fidelity of the computer model to the physical realities may vary, and should be assessed. Predicting indoor physical phenomena may require auxiliary flow and heat transfer models. The following aspects require special attention:

- Basic flow and heat transfer (convection, diffusion, conduction, and/or radiation)
- Turbulence models
- Auxiliary heat transfer and flow models
- Numerical methods
- Assessing CFD predictions

Whether a CFD code can be used to simulate an indoor environment depends on the flow and heat transfer features. For an indoor space with a baseboard heater, a CFD code that can solve natural convection flow may be sufficient. If a radiator replaces the baseboard heater, a radiation model is needed. When heat transfer through the walls must be considered, the code should have a conjugate heat transfer feature. When a duct supplies fresh air, room airflow becomes mixed convection, which requires the capability of mixed convection simulation. For indoor air quality studies, the code should be able to solve species concentrations. The more realistic the model is, the more complex the flow and heat transfer.

To verify a CFD code's capability of simulating the indoor environment of interest, review the code's manual and any libraries or examples provided by the developer to illustrate successful applications. Discussing the particular application with the code developer can ensure that the physical models required for the application are all available. However, even if a code has been found capable of simulating the physical phenomena in the indoor environment in the past, repeating the verification is helpful because success relies on the joint function of the user and the CFD code.

Hands-on verification usually starts with the simplest cases, which contain only one or two flow features and have been thoroughly tested to minimize uncertainties and errors. After successful verification, further simulations can be performed for more realistic cases, which may contain many key features of physical phenomena in an indoor space. The Reynolds or Rayleigh numbers can then be similar to those in reality.

Often, verification data are from high-precision experimental measurements. The quantity and quality of the experimental data are usually accompanied by quantified errors. They are generally accurate, have few human errors, cover a large area of interest in the CFD community, and are widely used for testing CFD simulations. These experimental data contain detailed information, such as boundary and initial conditions, and are usually two-dimensional.

Different cases represent different flow characteristics. Ideally, verification should be done for all flow features, but in practice, two to three important cases may be sufficient for most indoor environmental analyses.

Turbulence Model Identification. With a verification case identified, the next step is to identify a suitable turbulence model. These are divided into two groups: large eddy simulations (LES), and turbulent transport models [Reynolds-averaged Navier-Stokes (RANS) equation modeling]. LES divides turbulent flow into large-scale motion (calculated in LES) and small-scale motion (which must be modeled because of its effect on large-scale motion). Using a suitable subgrid scale model for the simulation is the most important factor, because the subgrid's accuracy and efficiency determines how correct and useful the LES is.

RANS models are more common in indoor airflow simulation. In general, eddy viscosity models are accurate for simple airflows, and Reynolds stress models are needed for complex flows. Complex flow exists in a flow domain with complex geometry, such as room and air supply diffuser geometry. Many CFD studies compare different turbulence models, so users may consult the literature for reported studies that are close to the case in question. The k-ε model is inaccurate for flows with adverse pressure gradient, which seriously limits its general usefulness. If comparisons for a particular case are not available, start with simple, popular models, such as the standard k-ε model (Launder and Spalding 1974), moving to progressively more complicated models if necessary. Vendors have made selecting different turbulence models as easy as a simple

Licensed for single user. © 2021 ASHRAE, Inc.

mouse click. However, a user should understand the principle of the model, its suitability for the problem to be solved, and the corresponding changes needed in using the model.

Identifying Auxiliary Heat Transfer and Flow Models. The indoor environment consists of very complicated physical phenomena, with radiative, conductive, and convective heat transfer almost always occurring simultaneously, and sometimes also including combustion, participating media radiation, and particle transport in multiple phases (air/liquid, air/solid, and air/liquid/solid). It is important to verify whether these physical phenomena can be modeled by a CFD code.

Separate verification of auxiliary models and turbulence models reduces the possibility of error. According to AIAA (1998), an error is "a recognizable deficiency in any phase or activity of modeling and simulation that is not due to lack of knowledge." A complex problem may be verified by separating it into several components that have analytical solutions. For example, a combined conductive, convective, and radiative heat transfer process can be verified by separating it into a conductive and radiative problem, and a convective problem. The two problems can then be verified by the relevant analytical solutions. Another example is liquid particle trajectory in indoor air quality simulations that involve condensation, evaporation, and collision, as well as strong interaction with airflow turbulence. The physical phenomena should be verified separately.

Verification does not ensure the correctness of the combined process. Therefore, uncertainty exists in the combined process. **Uncertainty** is a potential deficiency in any phase or activity of modeling caused by lack of knowledge; no highly accurate solutions are available. This may be addressed during validation.

Verification of numerical methods involves investigating the discretization of the continuous space and time (if transient) into finite intervals. The variables are computed at only a finite number of locations (**grid points**), so the continuous information contained in the solution of differential equations is replaced with discrete values. When a Cartesian mesh system is used for sloped or curved surfaces, the true geometry is not represented in the calculation because it would introduce an error. Thus, for sloped or curved surfaces, similar geometries must be verified rather restricting the simulation to empty rectangular rooms.

Different discretization schemes can be verified by comparing the results obtained from two different schemes. For example, to verify an unstructured grid system, Cartesian coordinates can be used as a reference. Case geometry should be simple, such as a rectangular room. Then, the two schemes should generate the same results. If the code has only one grid system, the discretization scheme verification can be combined with model verification.

Refining Grid Size and Time Step. Because CFD discretizes partial differential equations into discretized equations, this introduces an error. Verification of grid size and time step is done to reduce error to a level acceptable for the particular application. The time step applies only to transient flow simulation. Therefore, it is not sufficient to perform CFD computations on a single fixed grid. The difference in grid size and time step between two cases should be large enough to identify differences in CFD results. The common method is to repeat the computation by doubling the grid number, and compare the two solutions (Wilcox 1998). It is very important to separate numerical error from turbulence-model error, because the merits of different turbulence models cannot be objectively evaluated unless the discretization error of the numerical algorithm is known.

The geometry of an indoor space can be very complicated, and computer speed and capacity are still insufficient for simulating an indoor environment with very fine grid sizes (over a few million grids) and time steps (tens of thousands). Verification estimates the discretization error of the numerical solution. Theoretically, when grid size and time step approach zero, the discretization error of the numerical solution becomes negligible. For LES, when grid size and time step become small, flow in the subgrid scale is isotropic and the results become more accurate. When grid size is much smaller than the Kolmogorov length scale, the LES turns into a direct-numerical simulation.

Numerical Schemes, Iteration, and Convergence. A numerical scheme is important in CFD code to obtain a fast, accurate, and stable solution. A higher-order differencing scheme should be more accurate than a lower-order scheme for simple cases, such as those suggested for turbulence model verification. However, be aware of the limitations of various differencing schemes. For example, the central differencing scheme (accurate to the second order) is used for small Peclet numbers (Pe < 2), and the upwind scheme [accurate to the first order (but accounts for transportiveness)] is used for a high Peclet number. The Peclet number, the ratio of convection to conduction, is defined as

$$\mathrm{Pe} = LU\rho C_p/k \tag{28}$$

where C_p is specific heat.

Solution algorithms in CFD codes can be quite different, ranging from SIMPLE in conventional program with iteration, to the fast Fourier transformation for solving the Poisson pressure equation in LES without iteration. Iteration is normally needed in two situations: (1) globally for boundary value problems (i.e., over the entire domain), or (2) within each time step for transient physical phenomena. Criteria can be set to determine whether a converged solution is reached, such as a specified absolute and relative residual tolerance. The **residual** is the imbalance of solved variables (e.g., velocities, mass flow, energy, turbulence quantities, species concentrations). For indoor environment modeling, a CFD solution has converged if

$$\text{Residual for mass} = \frac{\text{Sum of absolute residuals in each cell}}{\text{Total mass inflow} < 0.1\%}$$

$$\text{Residual for energy} = \frac{\text{Sum of absolute residuals in each cell}}{\text{Total heat gains} < 1\%}$$

Similar convergence criteria can be defined for other solved variables, such as species concentration and turbulence parameters. Note that, for natural convection in a room, net mass flow is zero. Therefore, convergence has most likely been reached if there is little change (no change in the fourth digit) in the major dependent variables (temperature, velocities, and concentrations) within the last 100 iterations. However, a small relaxation factor can always give a false indication of convergence (Anderson et al. 1984).

To obtain stable and converged results, iteration often uses relaxation factors for different variables solved, such as underrelaxation factors and false time steps. Underrelaxation factors differ only slightly from false-time-steps.

Assessing CFD Predictions. A detailed qualitative and quantitative comparison of CFD results with data from experiments, analytical solutions, and direct numerical simulations is an important final step. All error analyses should be discussed in this section as well. The results indicate whether the CFD code can be used for indoor environment modeling.

Although this procedure divides verification into several parts, they often are integrated. The turbulence model and numerical technique must work together to obtain a correct CFD prediction for the flow features selected. However, it is necessary to break them down into individual items in some types of verifications, such as in CFD code development. Indoor environment designers often use commercial software, and it is logical to assume that the codes were verified during development. However, the verifications (if any) may have used different flows that are irrelevant to indoor airflow. In addition, a user may not fully understand the code's functions. It is imperative for the user to reverify a CFD code's capabilities for indoor

Licensed for single user. © 2021 ASHRAE, Inc.

environment simulations. This helps the user become more familiar with the code and eliminates human errors in using the code.

Generally, verification cases are not proprietary or restricted for security reasons; the data are usually available from the literature. It is strongly recommended that verification be reported when publishing CFD studies. This is especially helpful in eliminating user errors, because most CFD codes may have been validated by those cases. There are many examples of failed CFD simulations caused by user mistakes. Verification should be done for the following parameters:

- All variables solved by the governing equations (e.g., velocity, temperature, species concentrations)
- Boundary conditions (e.g., heat flux, mass inflow and outflow rates)

With these items verified, a CFD code should be able to correctly compute airflow and heat transfer encountered in an indoor environment. The level of accuracy depends on the criteria used in the verification. If the code failed to compute the flow correctly, the problem may be that (1) the code is incapable of solving the indoor airflows, (2) the code has bugs, or (3) there are errors in the user input data that defines the problem to be solved.

Validation

Validation demonstrates the ability of both the user and the code to accurately predict representative indoor environmental applications for which some sort of reliable data are available. It estimates how accurately the user can apply the code in simulating a full, real-world indoor environment problem, and gives the user the confidence to use the code for further applications, such as a design tool. A CFD code may solve the physical models selected to describe the real world, but may give inaccurate results because the selected models do not represent physical reality. For example, an indoor environment may simultaneously involve conduction, convection, and radiation, but a user may misinterpret the problem as purely convection. The CFD prediction may be correct for the convection part but fail to describe the complete physics involved. It is obviously a problem on the user's side, which validation process also tries to eliminate.

Note that *validation* addresses a complete flow and heat transfer system, or several subsystems that, together, represent a complete system. Although the procedure is almost the same, *verification* addresses only one of the flow aspects in an indoor environment.

The basic idea of validation is to identify suitable experimental data, to make sure that all important phenomena in the problem are correctly modeled, and to quantify the error and uncertainty in the CFD simulation. Because the primary role of CFD in indoor environment modeling is to serve as a high-fidelity tool for design and analysis, it is essential to have a systematic, rational, and affordable code validation process. Validation focuses on

- Confirming the capabilities of the turbulence model and other auxiliary models in predicting all the important physical phenomena associated with an indoor environment, before applying the CFD model for design and evaluation of a similar indoor environment category
- Confirming correctness of the discretization method, grid resolution, and numerical algorithm for flow simulation
- Confirming the user's knowledge of the CFD code and understanding of the basic physics involved

Ideally, validation should be performed for a complete indoor environment system that includes all important airflow and heat transfer physics and a full geometric configuration. Experimental data for a complete system can be obtained from on-site measurements or experiments in an environmental chamber. The data usually have a fairly high degree of uncertainty and large errors, and may contain little information about initial and boundary conditions. Reasonable assumptions are needed to make CFD simulation feasible.

Often, experimental data may not be available for a complete indoor environment system. In this case, validations for several subsystems or an incomplete system can be used. A subsystem represents some of the flow features in an indoor environment to be analyzed. The overall effect of several subsystems is equivalent to a complete system. For example, a complete indoor environment system consists of airflow and heat transfer in a room with occupants, furniture, and a forced air unit. If a user can correctly simulate several subsystems such as airflow and heat transfer (1) around a person, (2) in a room with obstacles, and (3) in a room with a forced air unit, the validation is acceptable. In the same example, an incomplete system for this environment can consist of airflow and heat transfer in a room with an occupant and a forced-air unit. Furniture, although it affects the indoor environment, is not as important as the other components, so validation with an incomplete system is acceptable. In either case, the key is that validation should lead to a solid confirmation of the combined capabilities of the user and code.

Although validation is for a complete indoor environment system, it is not necessary to start with a very complicated case if alternatives are available. Reliability is better for

- A simpler geometry, rather than a complicated one
- Convection, rather than combined convection, conduction, and radiation
- Single-phase flows, rather than multiphase flows
- Chemically inert materials, rather than chemically reactive materials

For complex physical phenomena in an indoor space, input data for CFD analysis may involve too much guesswork or imprecision. The available computer power may not be sufficient for high numerical accuracy, and the scientific knowledge base may be inadequate.

Complete system validation should be broken down into steps:

1. Setting up building geometry, and then placing inlets and outlets. Isothermal flow indicates the airflow pattern.
2. Adding heat transfer. Species concentration, particle trajectory, etc., should be considered later.

This progressive simulation procedure not only builds user confidence in performing the simulation, but also discovers some potential errors in the simulation.

If a CFD code has multiple choices, simple, popular models should be considered as the starting point for validation. The starting point can be as basic as

- Standard k-ε model
- No-auxiliary-flow and heat transfer models
- Structured mesh system
- Upwind scheme
- SIMPLE algorithm

The way of measuring real-world accuracy of the representation is to systematically compare CFD simulations to experimental data. The indoor environment systems used in validation are usually complicated, and the corresponding experimental data may contain bias errors and random errors, which should be reported as part of the validation. If the errors are unknown, a report on the equipment used in the measurements is helpful in assessing data quality. Although desirable, it is expensive and time-consuming to obtain good-quality data for a complete system. Therefore, reporting the CFD validation of the complete system cannot be overemphasized.

The criteria for accuracy when conducting a validation depend on the application. Very high accuracy, although desirable, is not essential because most design changes are incremental variations from a baseline. As long as the predicted trends are consistent, then

Licensed for single user. © 2021 ASHRAE, Inc.

less-than-perfect accuracy should be acceptable. The validation process should be flexible, allowing varying levels of accuracy, and be tolerant of incremental improvements as time and funding permit. The level of agreement achieved with the test data, taking into the account measurement uncertainties, should be reviewed in light of the CFD application requirements. For example, validation for modeling air temperature in a fire simulation requires much lower minimum accuracy than that for a thermal comfort study for an indoor environment.

If validation cases are simple and represent a subsystem of a complex indoor airflow, the validation criteria should be more restrictive than those for the complete system. The criteria can also be selective. For example, if correct prediction of air velocity is more important, the criteria for heat transfer may be relaxed. Although air velocity and temperature are interrelated, one parameter's effect on the other may be second-order. This allows a fast, less detailed model to be used, such as standard k-ε model, rather than a detailed but slower model, such as low-Reynolds-number model for heat transfer calculation in boundary layers.

Reporting CFD Results

Reporting involves summarizing CFD simulation results, while providing sufficient information on the value and quality of the CFD work. This is an important quality assurance strategy for CFD analysis of the indoor environment.

It is recommended to start with verification and then proceed to validation. In principle, reports for technical audiences should include the information discussed in the verification and validation sections, such as

- Experimental design
- CFD models and auxiliary heat transfer and flow models
- Boundary conditions
- Numerical methods
- Comparison of the CFD results with the data
- Drawing conclusions

The reporting format, however, can be flexible. If a report were intended for nontechnical readers, including only the last two items would be sufficient.

Experimental Design. Thermal and flow conditions of the test environment should be described in enough detail that other people could repeat the simulation. This can be as simple as a reference to the literature or a description of cases in the report. An analysis of uncertainties and errors in the experimental data or a short description of the experimental procedure and equipment should also be included.

CFD Models and Auxiliary Heat Transfer and Flow Models. CFD includes hundreds of different models of LES and RANS. Many popular turbulence models have been widely used and reported, making it unnecessary to provide detailed formulation. When reporting CFD results, it is important to specify which turbulence model is used. If the model has not been widely reported, detailed information (including why the model was selected) should be presented.

Indoor environment analysis may require auxiliary heat transfer and flow models. For example, a building may use porous material as insulation. Heat transfer through the insulation combines conduction, convection, and radiation (too complex a process for limited computer resources to simulate in detail). Instead, a lumped-parameter model may be used to combine the heat transfer processes and obtain accurate CFD results for the indoor environment. Therefore, it should be described in the CFD analysis report.

Boundary Conditions. Accurate specification of boundary conditions is crucial, because they indicate how the user interprets the specific physical phenomena into a computer model or mathematical equations that can be solved by the code. This interpretation requires the most skill in CFD modeling. Therefore, detailed description of boundary conditions can help others make informed assessments of the simulation's quality. Include the following information:

- **Geometry settings** (the size of the computational domain along with sizes and locations of all solid objects represented in the model). If there is an external wall involved that cannot be considered adiabatic, external ambient conditions (e.g., ambient temperature, external radiation temperature, convective heat transfer coefficient) should be reported as well.
- **Inlet**. Airflow from a diffuser greatly affects a room's airflow pattern. Diffuser geometry, and approximations are often used in a complete system to make indoor airflow solvable. Therefore, the CFD report should give detailed information on the approximations used, as well as the set boundary conditions for the inlet. In some situations, the exact location of an inlet may be difficult to identify (e.g., air infiltration from the outdoors to an indoor space could be through the cracks of windows and doors). Conditions may differ from one window to another. Also, infiltration flow rate can be difficult to estimate because wind magnitude and direction change over time. Furthermore, turbulence parameters for the inlet are generally unknown, and should be estimated. Therefore, how these "inlet" conditions are specified should be clearly stated.
- **Outlet**. An outlet has little effect on room airflow. However, conditions set for the outlet often can significantly influence numerical stability. For example, the outlet may become an inlet during iteration of a calculation. If the default outlet temperature is 0°C, this could lead to a diverged solution.
- **Walls**. Rigid surfaces in an indoor space, such as walls, ceilings, floors, and furniture surfaces, are all considered as walls. Very close to the wall, airflow is laminar, and convective heat transfer often occurs in this region between the flow and surfaces. Many turbulence models cannot accurately handle the laminar sublayer, so ad hoc solutions, such as damping functions, are often used. How a CFD code treats wall boundary conditions greatly affects the accuracy of numerical results. Even if the indoor space is large and the wall effect seems small, accurate prediction of heat transfer from the walls to room air is still important.
- **Open boundary**. When the area of interest is a part of the indoor space, the computational domain does not have to align with a rigid surface; instead, an "open" boundary can be defined. Depending on the inside and outside pressure difference, air may flow in or out across the open boundary.
- **Source/sink**. This boundary condition fixes thermal or dynamic parameters (e.g., heat flux from a wall to simulate solar radiation, total heat flow in the occupied zone to simulate heat dissipation from occupants, momentum source from an operating fan, species generation rate from contaminant sources) in a defined region. Describe the location, size, and parameter being specified.
- **Coupling between a micro and a macro model**. For a large indoor space, CFD analysis may be divided into micro and macro simulations. The micro simulation zooms into a particular area to reveal details of flow and thermal characteristic on a small scale compared with that for the entire space of interest. This allows finer-resolution examination of details of flow in that area. The macro simulation is applied to the entire flow system, and may use the results of the micro simulation so that a coarser grid system can be used. This coupling is usually a complicated procedure that should be detailed in the report.
- **Other approximations.** Approximations are almost always involved when representing the real world in a computer model. For example, when the surface temperature distribution of a heated object is not uniform, the CFD simulation may choose to neglect temperature variation on the surface. When designing a large stadium, it may not be feasible to simulate each individual spectator; instead, the model may combine all the spectators into a human

Licensed for single user. © 2021 ASHRAE, Inc.

layer. There are numerous examples in indoor environment modeling that need to be approximated in a CFD simulation. All approximations should be reported.

Numerical Methods. It is essential to report the numerical methods used in the analysis, although the report can be brief if the technique is popular and widely available from the literature. The numerical technique includes discretization technique, grid size and quality, time step, numerical schemes, iteration number, and convergence criteria. The report should briefly state why the technique was used, and how suitable it is to the problem under consideration. It is also important to provide the quality indices of the mesh of a body-fitted coordinate, because mesh quality affects the prediction's accuracy. Typically, these indices include normal distances from solid surfaces to the centers of the first adjacent cells, maximum scale ratios of each two neighboring cells in each coordinate, and smallest angle of mesh cells. The first index determines the prediction of boundary layer flows, and the other two indicate whether unacceptable numerical errors are introduced into the simulation. Because a coarse grid introduces more numerical viscosity, grid-refinement study is essential to achieving a grid-independent solution, and should be included in the CFD report. Although it may not be realistic to conduct grid refinement for the complete system, it should be conducted for benchmark cases, to estimate the errors introduced in the complete system.

If different numerical schemes have been tested, the results should be reported. Knowing the performance of different numerical schemes helps identify whether a numerical scheme or turbulence model causes a discrepancy between the CFD results and experimental data. Iteration number and convergence criteria are interrelated. It is better to use the sum of the absolute residual at each cell for all the variables as convergence criteria. The relaxation method and values should also be reported.

Comparison of Results with Data. The most important part of the report is comparing experimental data with analysis results. Qualitative values, such as airflow pattern, should be compared first, followed by first-order parameters, such as air velocity, temperature, and species concentrations. In general, both CFD results and experimental data are more accurate for first-order parameters. Second-order parameters, such as turbulence kinetic energy, Reynolds stresses, and heat fluxes, usually have greater uncertainties and errors than the first-order parameters in both the results and the experimental data, so seeking perfect agreement for these parameters is unnecessary.

It is insufficient to describe the comparison between CFD results and experimental data as *excellent*, *good*, *fair*, *poor*, or *unacceptable*. For example, a 20% difference can be considered excellent for a complex flow problem, but rather poor for two-dimensional forced convection in an empty room. Therefore, the comparison should be quantitative. The most useful information from comparison is how to interpret discrepancies. If there is little discrepancy, it is important to know why a turbulence model that uses approximations can predict the physical phenomena so well. The comparison should clearly state the uncertainties and errors of the experimental data, if they are known.

Conclusions. The most important findings of the CFD analysis should be presented as its conclusions, which should have broad applicability to indoor environment simulation. The report may also recommend measures for further improvements in CFD analyses.

2. MULTIZONE NETWORK AIRFLOW AND CONTAMINANT TRANSPORT MODELING

Multizone or network models are used to address airflow, contaminant transport, heat transfer, or some combination thereof. This section presents the mathematical and numerical background of network airflow and contaminant transport models. Thermal network models are addressed in Chapter 19.

2.1 MULTIZONE AIRFLOW MODELING

Theory

Network airflow models idealize a building as a collection of zones, such as rooms, hallways, and duct junctions, joined by flow paths representing doors, windows, fans, ducts, etc. Thus, the user assembles a building description by connecting zones via the appropriate flow paths.

The network model predicts zone-to-zone airflows based on the pressure-flow characteristics of the path models, and pressure differences across the paths. Three types of forces drive flow through the paths: wind, temperature differences (stack effect), and mechanical devices such as fans.

As shown in Figure 13, airflow network models resemble electrical networks. Airflow corresponds to electric current, with zone pressure acting like the voltage at an electrical node. Flow paths correspond to resistors and other electrical elements, including active elements like batteries (fans).

Unlike CFD models, network models do not prescribe details of airflow in zones. Thus, at any given time, each network zone is characterized by a single pressure. Pressure in the zone varies according to height, for example, using the simple hydrostatic relationship $P + \rho gh = \text{constant}$. Air density ρ is determined by the equation of state $\rho = P/(R_{air}T)$, based on the zone reference pressure P, temperature T, and the gas constant of the air mixture R_{air}. Zone temperature is given either directly by the user, or by an independent thermal model. The gas constant is typically assumed to be that of dry air, but can be made a function of other non-trace constituents as well (e.g., water vapor).

This lack of detail in the network zone models makes CFD preferable for predicting thermal comfort, or designing displacement ventilation systems, where airflow patterns in a room control the quantities of interest (Emmerich 1997).

In network airflow modeling, flow path models provide most of the modeling detail. Typically, the airflow rate $F_{j,i}$ from zone j to zone i, in kg/s, is some function of the pressure drop $P_j - P_i$ along the flow path:

$$F_{j,i} = f(P_j - P_i) \tag{29}$$

Various models represent different types of flow paths, but they are typically nonlinear. For example, the power-law model is commonly implemented as

$$Q = C(\Delta P)^n \tag{30}$$

where

$Q = F/\rho$ = volumetric airflow rate, m^3/s

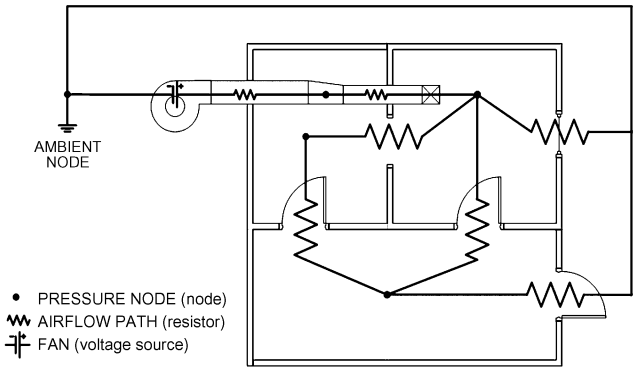

Fig. 13 Airflow Path Diagram

Licensed for single user. © 2021 ASHRAE, Inc.

ΔP = pressure drop across opening, Pa
C = flow coefficient, $(Pa^{1/n} \cdot m^3)/s$
n = flow exponent (typically 0.5 to 0.6)
ρ = density of air in flow path, kg/m^3

$\Delta P_{j,i}$ is assumed to be governed by the Bernoulli equation, which accounts for static pressure on each side of the flow path and pressure differences through the flow path caused by density and height changes. Static pressure at flow path connections depends on the zone pressures, again after accounting for height-dependent pressure changes in the zones. Where a flow path connects to the building facade, the pressure also may depend on pressure imposed by wind (see Chapters 16 and 24). Typically, the calculated pressure drop through a flow path neglects heat transfer and changes in kinetic energy, but this is not an inherent limitation of the model.

The power law model is based on engineering equations for orifice flow (see Chapter 16). Models for duct system components (e.g., dampers, bends, transitions) also follow the power law, with flow coefficient C given by tables (see Chapter 21). Other models describe the flow through doors and windows, fans, and so on (Dols and Walton 2002; Fuestel 1998).

The network airflow model combines the flow element and zone relations by enforcing mass conservation at each zone. The mass of air m_i in zone i is given by the ideal gas law

$$m_i = \rho_i V_i = \frac{P_i V_i}{R_{air} T_i} \tag{31}$$

where

m_i = mass of air in zone i, kg
ρ_i = zone density, kg/m^3
V_i = zone volume, m^3
P_i = zone pressure, Pa
T_i = zone temperature, K
R_{air} = gas constant for air = 287.055 J/(kg·K)

For a transient solution, the principle of conservation of mass states that

$$\frac{\partial m_i}{\partial t} = \rho_i \frac{\partial V_i}{\partial t} + V_i \frac{\partial \rho_i}{\partial t} = \sum_j F_{j,i} + F_i \tag{32}$$

$$\frac{\partial m_i}{\partial t} \approx \frac{1}{\Delta t}\left[\left(\frac{P_i V_i}{R_{air} T_i}\right)_t - (m_i)_{t-\Delta t}\right] \tag{33}$$

where

$F_{j,i}$ = airflow rate between zones j and i (positive values indicate flows from j to i; negative values indicate flows from i to j), kg/s
F_i = nonflow processes that could add or remove significant quantities of air flows from j to i; negative values indicate flows from i to j

However, airflows are typically calculated for steady-state conditions. This is reasonable for most cases where driving forces change slowly compared to the airflow (e.g., because of the building's large thermal mass, or because rate-limited actuators change damper and fan settings slowly compared to the rate at which the airflow system reestablishes a steady state). Under this quasi-steady assumption, mass conservation in zone i reduces to

$$\sum_j F_{j,i} = 0 \tag{34}$$

This model was based on the assumption that airflows were quiescent and that the zones' resistance to airflow was negligible relative to the resistance imposed by the airflow paths that connect the zones. Hence, the model enforces conservation of mass in each zone, but does not conserve momentum. This means it cannot model some effects, such as the suction that develops in one branch of a duct junction because of flow in another branch (see Chapter 21), or effects of zone geometry (e.g., short-circuiting of a room when a ventilation supply duct blows air directly into a return air intake). For momentum-based effects, a CFD model of the room is preferable to a network model.

Solution Techniques

In a nodal formulation of the network airflow problem, zone pressures drive the problem. Specifically, the solution algorithm chooses one reference pressure for each zone, and then finds the driving pressure drops across each flow path, after accounting for changes of height in both zones and flow paths. Applying the element pressure/flow relations yields each path's mass flow. Finally, these flows are summed for each zone to determine whether mass conservation is satisfied.

This approach leads to a set of algebraic mass balance equations that must be satisfied simultaneously for any given point in time. Because airflows depend nonlinearly on node pressures, these equations are nonlinear, and therefore must be solved iteratively using a nonlinear equation solver. The simultaneous set of mass balance equations is typically solved using the **Newton-Raphson method** to "correct" the zone reference pressures until the simultaneous mass balance of all flows is achieved. This method requires a **correction vector**, which depends on the partial derivatives of relationships between flow and pressure for all flow connections. Therefore, these flow-pressure relationships must be first-order differentiable (Feustel 1998; Walton 1989).

The Newton-Raphson method begins with an initial guess of the pressures. A new estimated vector of all zone pressures $\{\mathbf{P}\}^*$ is computed from the current estimate of pressures $\{\mathbf{P}\}$ by

$$\{\mathbf{P}\}^* = \{\mathbf{P}\} - \{\mathbf{C}\} \tag{35}$$

where the correction vector $\{\mathbf{C}\}$ is computed by the matrix relationship

$$[\mathbf{J}]\{\mathbf{C}\} = \{\mathbf{B}\} \tag{36}$$

where $\{\mathbf{B}\}$ is a column vector of total flow into each zone, with each element given by

$$\mathbf{B}_i = \sum_j F_{j,i} \tag{37}$$

$[\mathbf{J}]$ is the square (i.e., N by N for a network of N zones) Jacobian matrix whose elements are given by

$$\mathbf{J}_{i,j} = \sum_i \frac{\partial F_{j,i}}{\partial P_j} \tag{38}$$

In Equations (37) and (38), $F_{j,i}$ and $\partial F_{j,i}/\partial P_j$ are evaluated using the current estimate of pressure $\{\mathbf{P}\}$.

Equation (35) represents a set of linear equations which must be solved iteratively until a convergent solution of the set of zone pressures is achieved. In its full form, $[\mathbf{J}]$ requires computer memory for N^2 values, and a standard Gauss elimination solution has execution time proportional to N^3. Sparse matrix methods can be used to reduce both the storage and execution time requirements. Two solution methods for the linear equations have been successfully implemented: **Skyline** (also called the **profile method**) and **preconditioned conjugate gradient (PCG)**, which may be useful for problems with many zones and junctions (Dols and Walton 2002). The number of iterations needed to find a solution may be reduced by applying descent-based techniques to Newton-Raphson (Dennis and Schnabel 1996). Under a fairly modest set of conditions, line search methods are guaranteed to converge to a unique solution (Lorenzetti 2002).

Licensed for single user. © 2021 ASHRAE, Inc.

2.2 CONTAMINANT TRANSPORT MODELING

Fundamentals

Multizone contaminant transport models generally address transport of contaminants by advection via interzone airflows and mechanical system flows while accounting for some or all of the following: contaminant generation by various sources or chemical reaction, removal by filtration, chemical reaction, radiochemical decay, settling, or sorption of contaminants.

Unlike CFD models, the details of contaminant distribution within a zone are not modeled: each zone is considered well-mixed and characterized by a single concentration at any given point in time. Therefore, the well-mixed assumption's applicability to the mixing time and pattern of airflow in a zone should be considered. For example, the well-mixed assumption may be quite appropriate for zones with a mixing time well within the solution time step of interest (e.g., long-term off-gassing of building materials in common ventilation system configurations with relatively steady airflows). However, if a zone is characterized by steep concentration gradients and the time step of interest is relatively short (e.g., a chemical release in a relatively large zone), CFD analysis might be more appropriate. This is especially true if the reason for analysis is to resolve concentration gradients within the zone.

Solution Techniques

Generally, the goal is to solve a set of mass balance equations for each contaminant in each zone.

The mass of contaminant α in zone i is

$$m_{\alpha,i} = m_i C_{\alpha,i} \tag{39}$$

where m_i is the mass of air in zone i and $C_{\alpha,i}$ is the concentration mass fraction of α (kg of α/kg of air).

Contaminant is removed from zone i by

- Outward airflows from the zone at a rate of $\Sigma_j F_{i,j} C_{\alpha,j}$, where $F_{i,j}$ is the rate of air flow from zone i to zone j
- Removal at the rate $C_{\alpha,i} R_{\alpha,i}$ where $R_{\alpha,i}$ (kg of air/s) is a removal coefficient
- First-order chemical reactions with other contaminants $C_{\beta,i}$ (kg of β/kg of air) at rate $m_i \Sigma_\beta \kappa_{\alpha,\beta} C_{\beta,i}$, where $\kappa_{\alpha,\beta}$(1/s) is the kinetic reaction coefficient in zone i between species α and β

Contaminant is added to the zone by

- Inward airflows at rate $\Sigma_j (1 - \eta_{\alpha,j,i}) F_{j,i} C_{\alpha,j}$ where $\eta_{\alpha,j,i}$ is the filter efficiency in the path from zone j to zone i
- Generation at rate $G_{\alpha,i}$ (kg of α/s)
- Reactions of other contaminants

Conservation of contaminant mass for each species and assuming trace dispersal (i.e., $m_{\alpha,i} << m_i$) produces the following basic equation for contaminant dispersal for a given zone in a building:

$$\frac{dm_{\alpha,i}}{dt} = -R_{\alpha,i} C_{\alpha,i} - \sum_j F_{i,j} C_{\alpha,i} + \sum_j F_{i,j} (1 - \eta_{\alpha,j,i}) C_{\alpha,j} + m_i \sum_\beta \kappa_{\alpha,\beta} C_{\beta,i} + G_{\alpha,i} \tag{40}$$

This equation must be developed and solved for all zones to determine each contaminant's concentration. The various techniques for solving the ensuing set of equations can be categorized by the fundamental control volume used to develop them (i.e., Eulerian or Lagrangian), and by whether the analysis is geared towards solving the steady-state or dynamic system, or determining analytical solutions via eigen-analysis (Axley 1987, 1988; Dols and Walton 2002; Rodriguez and Allard 1992).

2.3 MULTIZONE MODELING APPROACHES

Simulation Planning

Planning can improve results and reduce the amount of input effort required in multizone simulations. The most important steps are determining what aspects of flow and contaminant transport are being studied, and what driving forces are likely to be most important.

One of the first decisions is defining zones in the model. The level of detail needed depends on both the building and scenario being modeled. For a study of contaminant transport from a garage into a house, separate zone models of clothes closets or kitchen cabinets are unnecessary and typically would only be needed if, for example, the source of the contaminant were inside the closet or cabinet. Because zones are typically broken where there are obstructions to air movement and/or differences in air properties, often a doorway between adjacent rooms is an appropriate place to define zones. Therefore, usually, a good starting point is to consider each room as a separate zone, and then model smaller enclosures in more detail or subdivide nonuniform rooms as necessary. On the other hand, sometimes the problem statement allows several rooms to be grouped together as a single zone. This is usually done to save user input time, because multizone models of even very large buildings can be quickly simulated on a desktop PC. HVAC system zoning also provides cues about how to group zones. Considering the primary driving forces (natural, mechanical, etc.) and the relative resistance of the flow elements that connect the zones to these forces can also be helpful. Starting with the assumption that each room is a zone, these changes can be made as the physics of the problem allow.

The type of simulation must also be determined. Are only airflow data necessary, or are contaminant concentrations also needed? Are the flow and contaminant transport problems steady-state, cyclical, or transient? Note that they may not be the same. Some models can simulate steady-state flow and transient contaminant transport.

During planning, the required model input data and boundary condition information must be specified, with the level of detail depending on the problem. Some items to consider are exterior envelope and interzonal leakage, weather conditions, wind pressure profiles, contaminant characteristics, contaminant source types and strengths, mechanical system flow rates, control algorithms, occupancy, and zone volumes.

Steps

The following process is typical of that used by experienced modelers to help catch mistakes and verify that the model is as intended. Always remember to save and test the model often.

1. **Input zones and building geometry**, using just enough detail to capture necessary information.
2. **Determine and specify building leakage.** This information may be obtained from blower door or tracer gas tests of the actual building, or estimated based on published data (see Chapter 16). Perform the following tests:
   - *Simulated blower door test*: Within the model, set all interior doors in the building to *open* and put a large pressurization fan in an exterior wall. Pressurize the building and use the fan's flow rate and consequent pressure difference across the exterior wall to calculate the leakage area per area of exterior wall. Verify specification of the proper amount of leakage on all walls by comparing inputs with data from an actual building or the literature. This is especially important when specifying individual leakage paths. If a result does not make sense, adjust leakage paths to see their effect on overall leakage.
   - *Simulation with typical weather boundary conditions*. Verify that the resulting infiltration rate is realistic.

Licensed for single user. © 2021 ASHRAE, Inc.

3. **Check stack effects.** Remove the blower door fan from the model, specify a very cold outdoor temperature, and run a simulation. Check the location of the **neutral pressure level**, which is the collection of points on the building envelope where the pressure difference with the outdoors is zero. The points usually form a plane at the building's midheight, though it may be a bit higher if roof leakage occurs with no corresponding floor leakage. A very high or low neutral pressure level could indicate large unintended leaks, probably somewhere near the neutral pressure level. (Note that, in complex operating systems or scenarios, the neutral pressure level may not form a plane and could change with time.)
4. **Specify wind and wind pressure profiles** on exterior leakage paths: Some programs allow wind specification, but this has no effect unless the wind pressure profile for each path is also specified. Perform the following tests:
   - *Run a simulation with no stack effect or mechanical system, and a high wind*. Flow should be visible through each exterior path. This allows quick identification of paths that may be missing a wind pressure profile.
   - *Verify that inflows and outflows are as prescribed* for the wind pressure profile. (For example, inflow on the windward side, outflow for walls at negative pressure) This helps verify that the pressure profile is correctly input and that the building and wind are oriented properly.
   - *Try other terrain conditions* to see if changing this variable significantly affects results.
5. **Input air-handling system(s)** (if any). Again, use only as much detail as is necessary. For small buildings, it may be reasonable to represent the air-handling system as a simple fan through an exterior wall for ventilation. For internal distribution from zone to zone, HVAC system flows in and out of each zone must be specified. Duct details should be included only if they are an important aspect of the problem. Sometimes supply and return vents can be placed in plenums or other locations where duct leakage is expected, to approximate duct leakage. However, if pressure-driven leakage must be modeled, the ducts should be specified in detail. Keep in mind that leakage in VAV systems, for example, should be separately specified upstream and downstream of the VAV box. Perform the following tests:
   - *Run a simulation with no stack or wind driving forces* and check outdoor, return, and exhaust air volumes to verify that the outside air is properly defined. This is a common beginner's mistake because there are several ways to specify outside air (e.g., setting a percentage of outside air, or scheduling outside air when the default may be 100%), and they may override one another. Also note that the amount of return air specified must equal or exceed the recirculation air needed. Otherwise, outdoor air may be used to make up the difference.
   - *Verify a realistic pressure difference across walls*. For example, a 50 Pa pressure difference would not occur in a real house, and probably indicates problems with either the system or leakage input. It is important that the magnitude of the pressure differences makes sense for the situation being modeled.
6. **Specify contaminants.** Contaminant sources are usually specified on either a mass or volume basis, although numerical counts (e.g., of particles, spores) can also be modeled and can typically be interchanged with mass units. Model refinement is often most appropriate and desirable near the contaminant source, where large concentration gradients are present. Simulation tests for pressure and velocity suggest the expected accuracy when a contaminant is added to the system. Transport of contaminants, particularly aerosols, is also influenced by other mechanisms, for which coefficients are specified in the basic transport equations.
   - *Verify that the model predicts conservation of contaminant mass* across multiple zones.
   - *Use experimental tracer analysis* using dynamically similar, nontoxic materials (if desired and feasible).
7. **Run a sensitivity analysis:** Deviations in some variables may need to be considered. Depending on the source of the input data and type of simulation, it is often good to know how the system performs over a range of certain variables. Possible items to consider include
   - *Formal sensitivity analysis*, if resources permit.
   - *Leakage dependence*, tested under a range of values. If conclusions are too leakage-dependent and leakage test data are not available, then a range of possible results should be considered.
   - *System pressure balance*. In a building with multiple air-handling systems, their design flow rates may imply perfect balance between systems; however, in real buildings, the balance will never be perfect, which can drive contaminants into shafts and distribute them through the building. Pressurizing or depressurizing a floor slightly compared to others (by specifying slightly imbalanced system flows) can illustrate how big this effect is.
   - *Weather effects*, which can be particularly important when studying infiltration or trying to maintain a pressure differential somewhere in the system. Verify that the system can accommodate the expected range of outdoor conditions.

2.4 VERIFICATION AND VALIDATION

Verification and validation of multizone models are similar in many regards to that of CFD models. Because the number of cases a complex multizone model can simulate is unlimited, Herrlin (1992) concluded that absolute validation is impossible. However, validation is still important to identify and eliminate large errors and to establish the model's range of applicability. Therefore, a model's performance should be evaluated under a variety of situations, with the recognition that predictions will always have a degree of uncertainty.

Herrlin lists three techniques of model validation:

- **Analytical verification** (comparison to simple analytically solved cases)
- **Intermodel comparison** (comparison of one model to another)
- **Empirical validation** (comparison to experimental tests)

Herrlin also discussed some specific difficulties in validating multizone airflow models, including input uncertainty (particularly of air leakage distribution) and attempting to simulate processes that cannot be modeled (e.g., using a steady-state airflow model to simulate dynamic airflow).

ASTM *Standard* D5157 provides information on establishing evaluation objectives, choosing data sets for evaluation, statistical tools for assessing model performance, and considerations in applying statistical tools. It stresses that data used for the evaluation process should be independent of the data used to develop the model. Also, sufficiently detailed information should be available for both the measured pollutant concentrations and the required input parameters. *Standard* D5157 also discusses the fact that model validation consists of multiple evaluations, with each evaluation assessing performance in specific situations.

Analytical Verification

Analytical verifications of multizone modeling tools are routinely performed to check the numerical solution. Analytical test cases are simple forms of problems that can be solved analytically to compare the model with an exact solution. For multizone models, these include airflow elements in series and parallel; stack effect; wind pressure effect; fan and duct elements; contaminant generation,

Licensed for single user. © 2021 ASHRAE, Inc.

dispersal, filtration, and deposition; and simple kinetic reactions. These tests are typically performed by model developers, but may be repeated by the user to develop confidence in the model and to verify the user's familiarity with the model. Such tests are not routinely published, but some were described by Walton (1989).

Unfortunately, most buildings are too complicated for the equations describing airflow and pollutant transport to be solved analytically. Therefore, analytical verification is of limited value in determining the adequacy of a multizone IAQ model for practical applications.

Intermodel Comparison

Intermodel comparison provides a relative check of different models' assumptions and numerical solutions. As with analytical verification, this is of limited value in evaluating a model's adequacy for practical applications. Generally, intermodel comparisons are not essential to a user, although good comparisons allow empirical validation conclusions to be generalized beyond the specific model studied.

Haghighat and Megri (1996) reported good agreement between CONTAM [the predecessor of CONTAMW (Dols and Walton 2002)], COMIS (Feustel et al. 1989), AIRNET (Walton 1989), CBSAIR (Haghighat and Rao 1991), and BUS (Tuomaala 1993) for airflow predictions for a four-zone model. The model building was two stories tall, with power-law flow elements for leakage. A single set of temperatures and wind-induced pressures was simulated. Model predictions for zone pressures and flow rates were within 5% and 13%, respectively.

Orme (2000) also found good agreement overall between CONTAM, COMIS, MZAP (unpublished), and BREEZE (BRE 1994) airflow predictions for a three-story building model. Power-law airflow elements were used to connect the four interior zones with each other and the ambient zone. A single wind speed and ambient temperature condition were applied. Note that both of these intermodel comparisons tested models for only a very limited range of conditions.

Empirical Validation

Empirical validation compares model assumptions and numerical solutions to indoor environmental problems of practical interest. However, the standard is only as accurate or realistic as the measurements used to produce it. Not only do all models have uncertainty, but all measurements do as well. Differences between model predictions and measurements could stem from errors in either set of data. As discussed in the section on CFD Modeling Approaches, comparison depends on the numerical model's capabilities and limiting assumptions, as well as the modeler's knowledge of both the model being applied and the indoor environment being modeled.

It is essential to apply valid statistical tools when interpreting comparisons of measurements and predictions. ASTM *Standard* D5157 provides three statistical tools for evaluating accuracy of IAQ predictions, and two additional statistical tools for assessing bias. Values for these statistical criteria are provided to indicate whether model performance is adequate. Note that the criteria and specific values in *Standard* D5157 are not ultimate arbiters of model accuracy, but they provide a useful template for the type of statistical analysis needed. Other valid statistical criteria may be substituted, with values appropriate for the accuracy needed for a specific project.

ASTM *Standard* D5157 suggests the following for assessing agreement between predictions:

- The correlation coefficient of predictions versus measurements should be 0.9 or greater.
- The line of regression between predictions and measurements should have a slope between 0.75 and 1.25 and an intercept less than 25% of the average measured concentration.

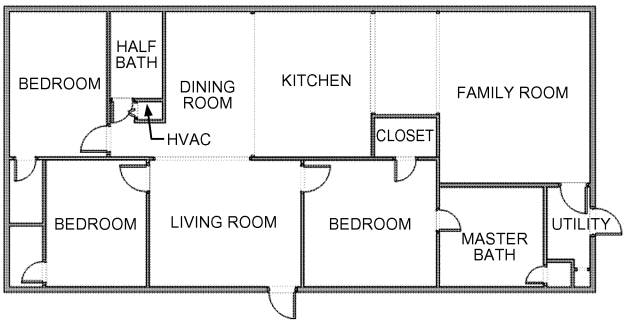

Fig. 14 Floor Plan of Living Area Level of Manufactured House

- The **normalized mean square error (NMSE)** should be less than 0.25. NMSE is calculated as

$$\text{NMSE} = \sum_{i=1}^{N}(C_{pi} - C_{oi})^2 / (n\bar{C}_o\bar{C}_p) \tag{41}$$

where C_p is the predicted concentration and C_o is the observed concentration.

For assessing bias,

1. The **normalized** or **fractional bias FB of mean concentrations** should be 0.25 or lower, and is calculated as

$$\text{FB} = 2(\bar{C}_p - \bar{C}_o)/(\bar{C}_p + \bar{C}_o) \tag{42}$$

2. The **fractional bias FS of variance** should be 0.5 or lower. FS is calculated as

$$\text{FS} = 2(\sigma^2\bar{C}_p - \sigma^2\bar{C}_o)/(\sigma^2\bar{C}_p + \sigma^2\bar{C}_o) \tag{43}$$

Emmerich (2001) reviewed the research literature for reports of empirical multizone model validation for residential-scale buildings. Few reviewed reports used either the ASTM *Standard* D5157 measures or other limited statistical evaluations to evaluate the results. However, for those cases with sufficient published data, Emmerich calculated several statistical measures from *Standard* D5157. Although these measures specifically address concentrations, they have been used to compare predicted and measured airflow rates also. Table 1 summarizes these published multizone model validation efforts.

There are many published validations for residential buildings, but far fewer for large commercial buildings because of the significant effort and cost involved in detailed measuring of a large building. Commercial studies are available by Furbringer et al. (1993), Said and MacDonald (1991), and Upham (1997).

Example 1. Ventilation Characterization of a New Manufactured House. Develop a multizone model to investigate various ventilation strategies of a new double-wide manufactured home consisting of three levels: crawlspace, living area, and attic. The crawlspace is divided into two sections by an insulated plastic belly; the region above the belly contains HVAC ductwork, and the volume below vents to the outdoors. The living area is shown in Figure 14. The attic comprises the volume above the vaulted ceiling, with five roof vents and eave vents spanning the perimeter of the house. Figure 15 provides a schematic of the house, showing connections between the levels and the air distribution system.

The building has an automated data acquisition system for monitoring air temperatures, building pressures, weather, and HVAC operation. The instrumentation system also has an automated tracer gas system for continuous monitoring of building air change rates. The tracer gas system injects sulfur hexafluoride into the house every 4 to 6 h, allows it to mix to a uniform concentration, and then monitors the

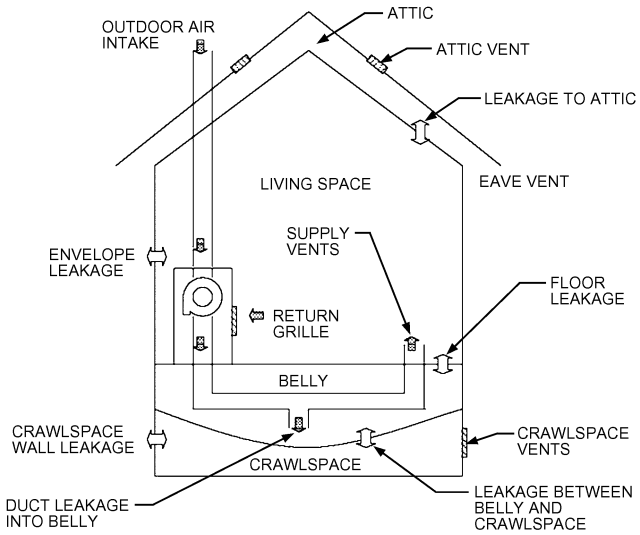

Fig. 15 Schematic of Ventilation System and Envelope Leakage

concentration decay in all the major zones of the building. Air change rates are then calculated based on the tracer gas decay rate in the living space.

Model Description. The model contains four levels: crawlspace, belly volume, living area (Figure 16), and attic. The duct modeling capabilities (see Figure 17 depicting belly level) were used to model the forced-air system. Leakage values of model airflow paths are listed in Table 2. Leaks in the living space envelope include the exterior wall and interfaces between the ceiling and wall, floor and wall, and the walls at the corners. In addition, there are two types of windows, the exterior doors, and the living space floor, which contains openings into the belly. There are also interior airflow paths, including leaks in the walls, doorframes, and open doors. Note that for all the tests and simulations performed, all interior doors were open. The attic has leakage in its floor (i.e., the ceiling of the living space), as well as the two types of attic vents to the outdoors. The crawlspace has leaks to the outdoors in the walls, vents in the front and rear of the house, and an access door. The model also includes a leak from the crawlspace into the belly. Finally, the duct leak into the belly, based on the described measurement, is included in the model.

Results. Tracer gas decay tests were simulated using the multizone model. Figure 18 shows the results of one of these simulations 30 min after injection of the tracer gas. The darker the shading, the higher the tracer gas concentration.

Figure 19A shows the measured and predicted air change rates with the forced-air system off as a function of indoor/outdoor air temperature difference under low wind speed conditions. Values predicted with the model are in good agreement with the measurements, particularly at low values of ΔT, but tend to underpredict by around 20% at higher values. Note that in all reported measurements and predictions, the outdoor air intake on the forced-air system and the window inlet vents are closed.

Figure 19B plots the measured and predicted air change rates with the forced-air system on, again for low wind speeds. Under positive temperature differences, the measured air change rates are actually lower than with the system off, which might not be expected with significant duct leakage. Airflow measurements indicate that the system moves about 450 L/s, but about 125 L/s is lost through duct leakage into the belly. Some of this airflow returns to the living space through leaks in the floor, but some flows through the crawlspace to the outdoors, which tends to depressurize the house. A significant air change rate is seen at zero ΔT, but this is not unexpected given the duct leakage. At higher values of ΔT, the stack effect "competes" with duct leakage into the belly, decreasing the air change rate into the house. This effect has actually been proposed as a means of controlling airflow and

contaminant entry from crawlspaces (Phaff and De Gids 1994). Overall, with the fan on, the agreement between the predicted and measured air change rates is quite good.

2.5 SYMBOLS

A_0 = diffuser effective area
B = ratio of intercept of regression line to average measured value
{B} = column vector of total flow into each zone
{C} = correction vector
C = flow coefficient, $(Pa^{1/n} \cdot m^3)/s$; concentration mass fraction
C_o = observed concentration
c_p = concentration in air
C_p = specific heat; predicted concentration
c_R = mean concentration in return openings
$C_{\alpha,i}$ = concentration mass fraction of α, kg_α/kg of air
C_μ = k-ε turbulence model constant
E = constant depending on wall roughness (9.8 for hydraulically smooth walls)
f = [see Equation (29)]
FB = fractional bias of mean concentrations
F_i = nonflow processes that could add or remove significant quantities of air
$F_{j,i}$ = mass flow rate from zone j to zone i, kg/s
FS = fractional bias of variance
g = gravitational acceleration
$G_{\alpha,i}$ = generation rate of contaminant α, kg_α/s
G_Δ = filter function
h = height; convective heat transfer coefficient
[J] = square Jacobian matrix
k = thermal conductivity; turbulent kinetic energy
l = turbulence length scale
L = characteristic length (e.g., room height, diffuser height)
m = mass of air, kg
M = slope of regression line
m_i = mass of air in zone i, kg
$\dot{m}$ = mass flow rate
n = flow exponent (typically 0.5 to 0.6)
NMSE = normalized mean square error
P = pressure
ΔP = pressure drop across opening, Pa
{P} = estimated pressures
{P*} = estimated vector of all zone pressures
Pe = Peclet number (ratio of convection to conduction)
P_i, P_j = zone pressure, Pa
Q = volumetric airflow rate, F/ρ, m^3/s
R = removal coefficient; correlation coefficient
R_{air} = gas constant of air, 287.055 J/(kg·K)

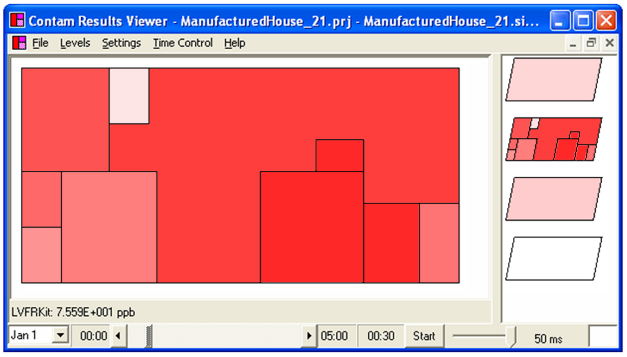

Fig. 18 Test Simulation of Concentration of Tracer Gas Decay in Manufactured House 30 min After Injection

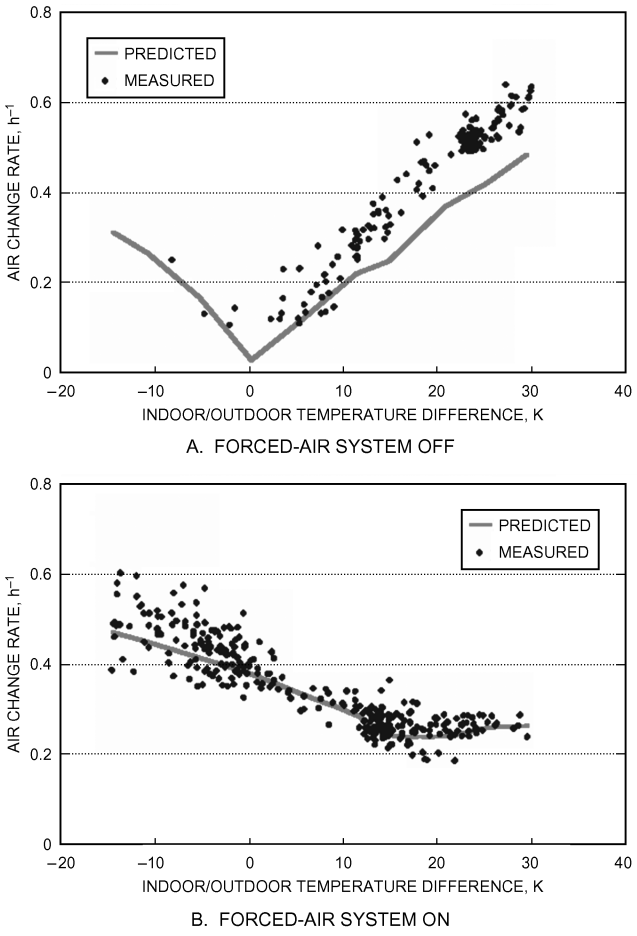

Fig. 19 Measured and Predicted Air Change Rates for Wind Speeds less than 2 m/s

Ra = Rayleigh number
Re = Reynolds number
s_{ij} = strain rate tensor
S_ϕ = source or sink
t = time, s
T = temperature, °C
ΔT = temperature change
TI = turbulence intensity, %
T_s = surface temperature

Table 2 Leakage Values of Model Airflow Components

	Exterior Airflow Paths	ELA at 4 Pa
Living space envelope	Exterior wall	14 mm²/m²
	Ceiling wall interface	81 mm²/m
	Floor wall interface	124 mm²/m
	Window #1	500 mm²
	Window #2	194 mm²
	Corner interface	80.8 mm²/m
	Exterior doors	1870 mm²
	Living space floor to belly volume	365 mm²/m²
Interior airflow paths	Interior walls	200 mm²/m²
	Bedroom doorframe	4100 mm²
	Open interior doors	2 by 0.9 m
	Bathroom doorframe	3300 mm²
	Interior doorframe	2500 mm²
	Closet doorframe	460 mm²
Attic	Attic floor	200 mm²/m²
	Roof vents	0.135 m²
	Eave vents	10 600 mm²/m
Crawlspace and belly	Exterior walls of crawlspace	2500 mm²/m²
	Rear crawlspace vents	32 300 mm²
	Front crawlspace vents	46 500 mm²
	Crawlspace access door	20 600 mm²
	Crawlspace to belly	25 800 mm²
	Duct leak into belly	3200 mm²

T_i = zone temperature, K
U = velocity
u_i = instantaneous velocity
$\bar{u}_i$ = ensemble average of v for steady flow
u'_i = fluctuation velocity
u_j = velocity in j direction, m/s
U_P = velocity parallel to wall at ΔY_p
U_{ref} = mean stream velocity
U_0 = air supply velocity for momentum source
V_i = zone volume, m³
x_i = distance in i direction, m
x_j = distance in j direction, m
Y^+ = dimensionless distance from wall
ΔY_p = distance from wall to center of first cell

Greek

α, β = contaminants
Γ_ϕ = generalized diffusion coefficient or transport property of fluid flow
ε = dissipation rate of turbulent kinetic energy
η = Kolmogorov length scale; filter efficiency
κ = von Karmann's constant (0.41)
$\kappa_{\alpha,\beta}$ = kinetic reaction coefficient between α and β
μ = dynamic viscosity
μ_t = eddy viscosity
ν = kinematic viscosity
ρ = density, kg/m³
ρ_i = zone density, kg/m³
σ = standard deviation
τ_{ij} = viscous tensor stress
τ_w = wall shear stress
ϕ = transport property (1 for mass continuity, momentum, temperature, or species concentration)

CHAPTER 14

CLIMATIC DESIGN INFORMATION

Climatic Design Conditions 14.1
Calculating Clear-Sky Solar Radiation 14.8
Transposition to Receiving Surfaces of Various Orientations 14.10
Generating Design-Day Data 14.12
Estimation of Degree-Days 14.12
Representativeness of Data and Sources of Uncertainty 14.13
Other Sources of Climatic Information 14.16

THIS chapter and the accompanying data summaries in PDF format provide the climatic design information for 9237 locations in the United States, Canada, and around the world. This is an increase of 1119 stations from the 2017 *ASHRAE Handbook—Fundamentals*. As in previous editions, the large number of stations made printing the whole tables impractical. Consequently, the complete table of design conditions for only an "example city" appears in this printed chapter to illustrate the table format. However, a subset of the table elements most often used is presented in the Appendix at the end of this chapter for selected stations representing major urban centers in the United States, Canada, and around the world. The complete data tables for all 9237 stations are included with both the PDF version of this chapter (downloadable from technologyportal.ashrae.org) and the Handbook Online version.

This climatic design information is commonly used for design, sizing, distribution, installation, and marketing of heating, ventilating, air-conditioning, and dehumidification equipment, as well as for other energy-related processes in residential, agricultural, commercial, and industrial applications. These summaries include values of dry-bulb, wet-bulb, and dew-point temperature, and wind speed with direction at various frequencies of occurrence. Also included are monthly degree-days to various bases, parameters to calculate clear-sky irradiance, and monthly averages of daily all-sky solar radiation. Sources of other climate information of potential interest to ASHRAE members are described later in this chapter.

Design information in this chapter was developed largely through research project RP-1847 (Roth 2021). The information includes design values of dry-bulb with mean coincident wet-bulb temperature, design wet-bulb with mean coincident dry-bulb temperature, and design dew-point with mean coincident dry-bulb temperature and corresponding humidity ratio. These data allow the designer to consider various operational peak conditions. Design values of wind speed facilitate the design of smoke management systems in buildings (Lamming and Salmon 1996, 1998).

Warm-season temperature and humidity conditions are based on annual percentiles of 0.4, 1.0, and 2.0. Cold-season conditions are based on annual percentiles of 99.6 and 99.0. The use of annual percentiles to define design conditions ensures that they represent the same probability of occurrence in any climate, regardless of the seasonal distribution of extreme temperature and humidity.

Monthly precipitation data are also included. They are used mostly to determine climate zones for ASHRAE *Standard* 169, but may also be helpful in developing green technologies such as vegetative roofs and stormwater harvesting.

The clear-sky solar radiation model introduced in the 2009 edition and slightly modified in the 2013 edition is unchanged in its general formulation. However, the site-specific coefficients have been recalculated, based on the latest atmospheric information available. All-sky solar radiation values are also provided; these are useful in assessing solar technologies (solar heating, photovoltaics), which are typically necessary in the quest for designing net-zero-energy buildings.

The preparation of this chapter is assigned to TC 4.2, Climatic Information.

Recent trends for a few specific elements are also listed. Although they reflect the evolution of climatic design conditions in the recent past, they are not necessarily good indicators for future trends related to climate change or other anthropogenic factors. However, they clearly make users aware of the current evolution of climate worldwide, with a general trend towards higher temperatures.

Design conditions are provided for locations for which long-term hourly observations were available (1994-2019 for most stations). Compared to the 2017 chapter, the number of U.S. stations increased from 1952 to 2220 (14% increase); Canadian stations increased from 765 to 841 (10% increase); and stations in the rest of the world increased from 5401 to 6167 (14% increase; see Figure 1 for map).

1. CLIMATIC DESIGN CONDITIONS

Table 1 shows climatic design conditions for Atlanta, GA, to illustrate the format of the data available on the CD-ROM. A limited subset of these data for 1445 of the 8118 locations for 21 annual data elements is provided for convenience in the Appendix.

The top part of the table contains station information as follows:

- Name of the observing station, state (USA) or province (Canada), country.
- World Meteorological Organization (WMO) station identifier.
- Weather Bureau Army Navy (WBAN) number (99999 denotes missing).
- Latitude of station, °N/S.
- Longitude of station, °E/W.
- Elevation of station, m.
- Standard pressure at elevation, in kPa (see Chapter 1 for equations used to calculate standard pressure).
- Time zone, h ± UTC.
- Time zone code (e.g., NAE = Eastern Time, USA and Canada). The CD-ROM contains a list of all time zone codes used in the tables.
- Period analyzed (e.g., 90-14 = data from 1990 to 2014 were used).

Annual Design Conditions

Annual climatic design conditions are contained in the first three sections following the top part of the table. They contain information as follows:

Annual Heating and Humidification Design Conditions.

- Coldest month (i.e., month with lowest average dry-bulb temperature; 1 = January, 12 = December).
- Dry-bulb temperature corresponding to 99.6 and 99.0% annual cumulative frequency of occurrence (cold conditions), °C.
- Dew-point temperature corresponding to 99.6 and 99.0% annual cumulative frequency of occurrence, °C; corresponding humidity ratio, calculated at standard atmospheric pressure at elevation of station, grams of moisture per kg of dry air; mean coincident dry-bulb temperature, °C.
- Wind speed corresponding to 0.4 and 1.0% cumulative frequency of occurrence for coldest month, m/s; mean coincident dry-bulb temperature, °C.

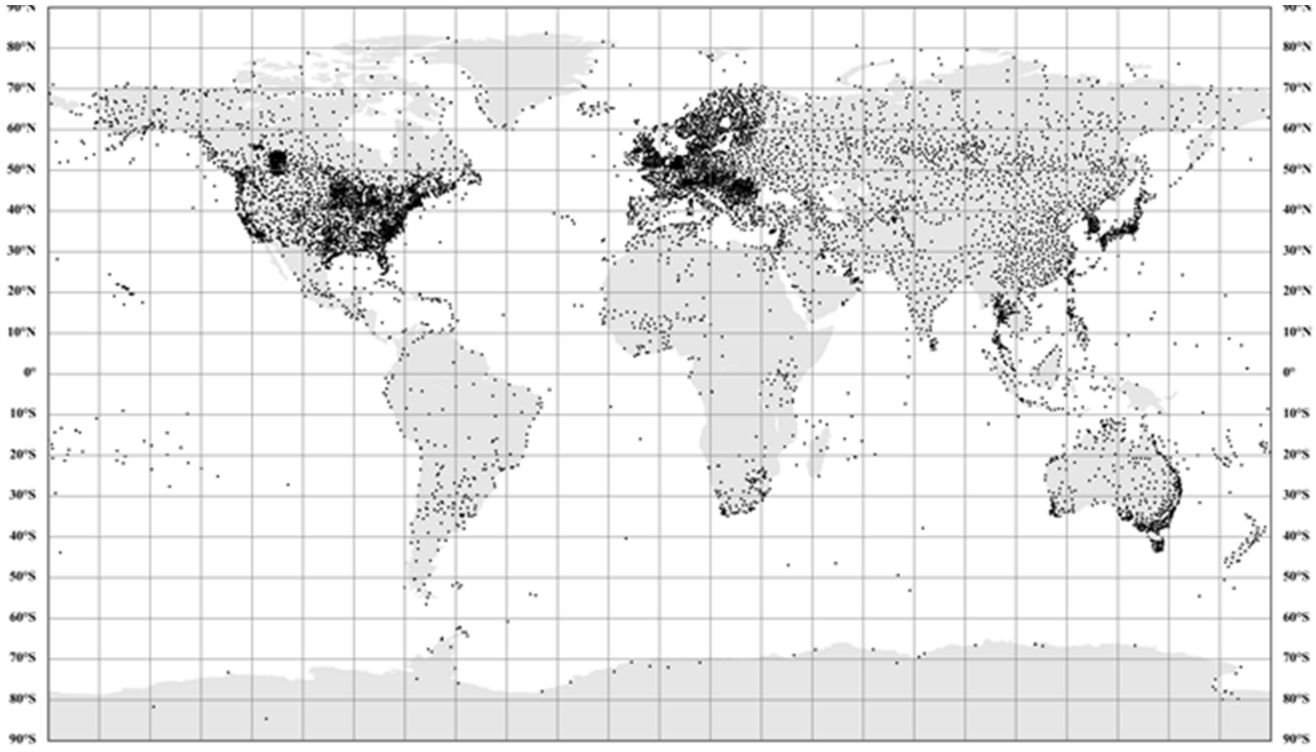

Fig. 1 Locations of Weather Stations

Licensed for single user. © 2021 ASHRAE, Inc.

- Mean wind speed coincident with 99.6% dry-bulb temperature, m/s; corresponding most frequent wind direction, degrees from north (east = 90°).

Annual Cooling, Dehumidification, and Enthalpy Design Conditions.

- Hottest month (i.e., month with highest average dry-bulb temperature; 1 = January, 12 = December).
- Daily temperature range for hottest month, °C [defined as mean of the difference between daily maximum and daily minimum dry-bulb temperatures for hottest month].
- Dry-bulb temperature corresponding to 0.4, 1.0, and 2.0% annual cumulative frequency of occurrence (warm conditions), °C; mean coincident wet-bulb temperature, °C.
- Wet-bulb temperature corresponding to 0.4, 1.0, and 2.0% annual cumulative frequency of occurrence, °C; mean coincident dry-bulb temperature, °C.
- Mean wind speed coincident with 0.4% dry-bulb temperature, m/s; corresponding most frequent wind direction, degrees true from north (east = 90°).
- Dew-point temperature corresponding to 0.4, 1.0, and 2.0% annual cumulative frequency of occurrence, °C; corresponding humidity ratio, calculated at the standard atmospheric pressure at elevation of station, grams of moisture per kg of dry air; mean coincident dry-bulb temperature, °C.
- Enthalpy corresponding to 0.4, 1.0, and 2.0% annual cumulative frequency of occurrence, kJ/kg; mean coincident dry-bulb temperature, °C.
- Extreme maximum wet-bulb temperature, °C.

Extreme Annual Design Conditions.

- Wind speed corresponding to 1.0, 2.5, and 5.0% annual cumulative frequency of occurrence, m/s.
- Mean and standard deviation of extreme annual minimum and maximum dry-bulb temperature, °C.
- 5-, 10-, 20-, and 50-year return period values for minimum and maximum extreme dry-bulb temperature, °C.
- Mean and standard deviation of extreme annual minimum and maximum wet-bulb temperature, °C.
- 5-, 10-, 20-, and 50-year return period values for minimum and maximum extreme wet-bulb temperature, °C.

Monthly Design Conditions

Monthly design conditions are divided into subsections as follows:

Temperatures, Degree-Days, and Degree-Hours.

- Average temperature, °C. This parameter is a prime indicator of climate and is also useful to calculate heating and cooling degree-days to any base.
- Standard deviation of average daily temperature, °C. This parameter is useful to calculate heating and cooling degree-days to any base. Its use is explained in the section on Estimation of Degree-Days.
- Heating and cooling degree-days (bases 10 and 18.3°C). These parameters are useful in energy estimating methods. They are also used to classify locations into climate zones in ASHRAE *Standard* 169.
- Cooling degree-hours (bases 23.3 and 26.7°C). These are used in various standards, such as *Standard* 90.2-2004.

Wind.

- Monthly average wind speed, m/s. This parameter is useful to estimate the wind potential at a site; however, the local topography may significantly alter this value, so close attention is needed.

Precipitation.

- Average precipitation, mm. This parameter is used to calculate climate zones for *Standard* 169, and is of interest in some green building technologies (e.g., vegetative roofs).
- Standard deviation of precipitation, mm. This parameter indicates the variability of precipitation at the site.
- Minimum and maximum precipitation, mm. These parameters give extremes of precipitation and are useful for green building technologies and stormwater management.

Monthly Design Dry-Bulb, Wet-Bulb, and Mean Coincident Temperatures.

These values are derived from the same analysis that results in the annual design conditions. The monthly summaries are useful when seasonal variations in solar geometry and intensity, building or facility occupancy, or building use patterns require consideration. In particular, these values can be used when determining air-conditioning loads during periods of maximum solar radiation. The values listed in the tables include

- Dry-bulb temperature corresponding to 0.4, 2.0, 5.0, and 10.0% cumulative frequency of occurrence for indicated month, °C; mean coincident wet-bulb temperature, °C.
- Wet-bulb temperature corresponding to 0.4, 2.0, 5.0, and 10.0% cumulative frequency of occurrence for indicated month, °C; mean coincident dry-bulb temperature, °C.

For a 30-day month, the 0.4, 2.0, 5.0 and 10.0% values of occurrence represent the value that occurs or is exceeded for a total of 3, 14, 36, or 72 h, respectively, per month on average over the period of record. Monthly percentile values of dry- or wet-bulb temperature may be higher or lower than the annual design conditions corresponding to the same nominal percentile, depending on the month and the seasonal distribution of the parameter at that location. Generally, for the hottest or most humid months of the year, the monthly percentile value exceeds the design condition for the same element corresponding to the same nominal percentile. For example, Table 1 shows that the annual 0.4% design dry-bulb temperature at Atlanta, GA, is 34.4°C; the 0.4% monthly dry-bulb temperature exceeds 34.4°C for June, July, and August, with values of 34.7, 36.4, and 36.3°C, respectively. Fifth and tenth percentiles are also provided to give a greater range in the frequency of occurrence, in particular providing less extreme options to select for design calculations.

A general, very approximate rule of thumb is that the n% annual cooling design condition is roughly equivalent to the 5n% monthly cooling condition for the hottest month; that is, the 0.4% annual design dry-bulb temperature is roughly equivalent to the 2% monthly design dry-bulb temperature for the hottest month; the 1% annual value is roughly equivalent to the 5% monthly value for the hottest month, and the 2% annual value is roughly equivalent to the 10% monthly value for the hottest month.

Mean Daily Temperature Range. These values are useful in calculating daily dry- and wet-bulb temperature profiles, as explained in the section on Generating Design-Day Data. Three kinds of profile are defined:

- Mean daily temperature range for month indicated, °C (defined as mean of difference between daily maximum and minimum dry-bulb temperatures).
- Mean daily dry- and wet-bulb temperature ranges coincident with the 5% monthly design dry-bulb temperature. This is the difference between daily maximum and minimum dry- or wet-bulb temperatures, respectively, averaged over all days where the maximum daily dry-bulb temperature exceeds the 5% monthly design dry-bulb temperature.
- Mean daily dry- and wet-bulb temperature ranges coincident with the 5% monthly design wet-bulb temperature. This is the difference between daily maximum and minimum dry- or wet-bulb temperatures, respectively, averaged over all days where the maximum daily wet-bulb temperature exceeds the 5% monthly design wet-bulb temperature.

Clear-Sky Solar Irradiance. Clear-sky irradiance parameters are useful in calculating solar-related air conditioning loads for any time of any day of the year. Parameters are provided for the 21st day of each month. The 21st of the month is usually a convenient day for solar calculations because June 21 and December 21 represent the solstices (longest and shortest days) and March 21 and September 21 are close to the equinox (days and nights have the same length). Parameters listed in the tables are

- Clear-sky optical depths for beam and diffuse irradiances, which are used to calculate beam and diffuse irradiance as explained in the section on Calculating Clear-Sky Solar Radiation.
- Clear-sky beam normal and diffuse horizontal irradiances at solar noon. These two values can be calculated from the clear-sky optical depths but are listed here for convenience.

All-Sky Solar Radiation. All-sky solar radiation parameters are useful for evaluating the potential of solar technologies (e.g., solar heating, photovoltaics), which are valuable in the design of net-zero energy buildings. Parameters listed in the tables are

- Monthly average daily global radiation on a horizontal surface. This is a traditional way to characterize the solar resource at a site.
- Standard deviation of monthly average daily radiation on a horizontal surface. This parameter gives an idea of the year-to-year variability of the solar resource at the site.

Data Sources

The following primary sources of observational data sets were used in calculating design values:

- For most Canadian stations, meteorological data were obtained directly from Environment Canada (climate.weather.gc.ca) for the years 1982-2014.
- Data were obtained from the U.S. Climate Reference Network (CRN) (www.ncdc.noaa.gov/crn) (Diamond et al. 2013).
- Most stations, including some in Canada with inadequate data, were sourced through the Integrated Surface Database (ISD) from NOAA (www.ncdc.noaa.gov) (Smith et al. 2011) for the years 1982-2015.

In most cases, the period of record used in the calculations spanned 25 years (1990 to 2014). This choice of period is a compromise between trying to derive design conditions from the longest possible period of record, and using the most recent data to capture climatic or land-use trends from the past two decades. The actual number of years used in the calculations for a given station depends on the amount of missing data, and, as discussed in the next section, may be as little as 8 years. The first and last years of the period of record used to calculate design conditions are listed in the top section of the tables of climatic design conditions, as shown in Table 1 for Atlanta. For a limited number of stations, years as far back as 1982 or as recent as 2015 were used instead of 1990 to 2014 because that time frame lacked the necessary data.

Precipitation data were derived from a number of sources, including station data from the Global Historical Climatology Network, version 2 (GHCN 2015) and the United Nations Food and Agriculture Organization (FAO 2011), as well as gridded data from the Global Precipitation Climatology Centre, version 7 (GPCC 2015), and the Global Precipitation Climate Project (GPCP).

Clear-sky solar irradiance parameters listed in the tables constitute a simple parameterization of the more sophisticated REST2 broadband clear-sky radiation model (Gueymard 2008; Gueymard

Table 1A Nomenclature for Tables of Climatic Design Conditions

CDD*n*	Cooling degree-days base n°C, °C-day
CDH*n*	Cooling degree-hours base n°C, °C-hour
DB	Dry-bulb temperature, °C
DBAvg	Average daily dry-bulb temperature, °C
DBSD	Standard deviation of average daily dry-bulb temperature, °C
DP	Dew-point temperature, °C
Ebn,noon	Clear-sky beam normal irradiances at solar noon, W/m^2
Edh,noon	Clear-sky diffuse horizontal irradiance at solar noon, W/m^2
Elev	Elevation, m
Enth	Enthalpy, kJ/kg base 0°C and 101.325 kPa pressure
HDD*n*	Heating degree-days base, n°C, °C-day
HR	Humidity ratio, $g_{moisture}/kg_{dry\ air}$
Lat	Latitude, °N
Long	Longitude, °E
MCDB	Mean coincident dry-bulb temperature, °C
MCDBR	Mean coincident dry-bulb temp. range, °C
MCWB	Mean coincident wet-bulb temperature, °C
MCWBR	Mean coincident wet-bulb temp. range, °C
MCWS	Mean coincident wind speed, m/s
MDBR	Mean dry-bulb temp. range, °C
PCWD	Prevailing coincident wind direction, ° (0 = North; 90 = East)
Period	Years used to calculate the design conditions
PrecAvg	Average precipitation, mm
PrecMax	Maximum precipitation, mm
PrecMin	Minimum precipitation, mm
PrecStd	Standard deviation of precipitation, mm
RadAvg	Monthly mean daily all-sky radiation, kWh/(m^2·day)
RadStd	Standard deviation of monthly mean daily radiation, kWh/m^2·day
StdP	Standard pressure at station elevation, kPa
taub	Clear-sky optical depth for beam irradiance
taud	Clear-sky optical depth for diffuse irradiance
Time Zone	Hours ahead or behind UTC, and time zone code
WB	Wet-bulb temperature, °C
WBAN	Weather Bureau Army Navy number
WMO#	Station identifier from the World Meteorological Organization
WS	Wind speed, m/s
WSAvg	Monthly average wind speed, m/s

Note: Numbers *(1)* to *(45)* and letters *(a)* to *(p)* are row and column references to quickly point to an element in the table. For example, the 5% design wet-bulb temperature for July can be found in row *(31)*, column *(k)*.

and Thevenard 2009; Thevenard 2009). The REST2 model requires detailed knowledge of various atmospheric constituents, such as aerosols, water vapor, or ozone. To extend applicability of the model to the whole world, multiple data sets, mainly derived from space observations and reanalysis models, were used to obtain these inputs. These sources of data have changed or have been updated since the 2013 edition, which explains the coincident changes in site-specific coefficients. Water vapor, ozone, and ground albedo data are now derived from the National Aeronatucis and Space Administration (NASA) Modern-Era Retrospective Analysis for Research and Applications, version 2 (MERRA-2) reanalysis dataset (Molod et al. 2015), corrected for elevation in the case of water vapor (Gueymard and Thevenard 2009). The period of data is now uniform and longer, from 2000 to 2014. An exception is nitrogen dioxide, for which a database from Ozone Monitoring Instrument (OMI) satellite observations (aura.gsfc.nasa.gov/omi.html) is used over the period 2005 to 2014. Pressure is estimated from station's elevation.

Aerosol turbidity data (in the form of separate evaluations of aerosol optical depth and Ångström exponent) received special attention, because they are the primary inputs that affect the accuracy of direct and diffuse irradiance predictions under clear skies. Spaceborne retrievals of aerosol optical depth at various wavelengths from NASA's Multi-angle Imaging SpectroRadiometer (MISR; www-misr.jpl.nasa.gov) and two Moderate Resolution Imaging Spectroradiometer (MODIS; modis-atmos.gsfc.nasa.gov) instruments were used between 2000 and 2014 and compared to reference data from a large number of ground-based sites, mostly from the Aerosol Robotic Network (AERONET; aeronet.gsfc.nasa.gov), after appropriate scale-height corrections to remove artifacts from the effect of elevation (Gueymard and Thevenard 2009). Regional corrections of the satellite data were devised to remove as much bias as possible, compared to the reference ground-based data. To fill missing data or correct biased satellite observations, modeled aerosol datasets were used, including 10 years (2003 to 2012) of simulated monthly-average aerosol optical depth from the Monitoring Atmospheric Composition and Climate (MACC) reanalysis model (Eskes et al. 2015; Inness et al. 2013) and 13 years (2002 to 2014) of MERRA-2 reanalysis data (Molod et al. 2015). Results from the REST2 model (Gueymard 2008) were then fitted to the simple two-parameter model described in this chapter. The fits enable a concise formulation requiring tabulation, on a monthly basis, of only two parameters per station, referred to here as the clear-sky beam and diffuse optical depths. Details about the fitting procedure can be found in Thevenard and Gueymard (2013).

Global horizontal irradiance at the surface, and its standard deviation, were calculated from the Clouds and the Earth's Radiant Energy System (CERES) Energy Balanced and Filled (EBAF) dataset (ceres.larc.nasa.gov/products.php?product=EBAF-Surface). From the available 1°×1° dataset, a bilinear interpolation, without altitude adjustment, was made given the station latitude and longitude for the period 2000 to 2014.

Calculation of Design Conditions

Values of ambient dry-bulb, dew-point, and wet-bulb temperature and wind speed corresponding to the various annual percentiles represent the value that is exceeded on average by the indicated percentage of the total number of hours in a year (8760). The 0.4, 1.0, 2.0, and 5.0% values are exceeded on average 35, 88, 175, and 438 h per year, respectively, for the period of record. The design values occur more frequently than the corresponding nominal percentile in some years and less frequently in others. The 99.0 and 99.6% (cold-season) values are defined in the same way but are usually viewed as the values for which the corresponding weather element is less than the design condition for 88 and 35 h, respectively.

Simple design conditions were obtained by binning hourly data into frequency tables, then deriving from the binned data the design condition having the probability of being exceeded a certain percentage of the time. Mean coincident values were obtained by double-binning the hourly data into joint frequency matrices, then calculating the mean coincident value corresponding to the simple design condition.

Coincident temperature ranges were also obtained by double-binning daily temperature ranges (daily maximum minus minimum) versus maximum daily temperature. The mean coincident daily range was then calculated by averaging all bins above the simple design condition of interest.

The weather data sets used for the calculations often contain missing values (either isolated records, or because some stations report data only every third hour). Gaps up to 6 h were filled by linear interpolation to provide as complete a time series as possible. Dry-bulb temperature, dew-point temperature, station pressure, and

Licensed for single user. © 2021 ASHRAE, Inc.

humidity ratio were interpolated. However, wind speed and direction were not interpolated because of their more stochastic and unpredictable nature.

Some stations in the ISD data set also provide data that were not recorded at the beginning of the hour. When data at the exact hour were missing, they were replaced by data up to 0.5 h before or after, when available.

Finally, psychrometric quantities such as wet-bulb temperature or enthalpy are not contained in the weather data sets. They were calculated from dry-bulb temperature, dew-point temperature, and station pressure using the psychrometric equations in Chapter 1.

Measures were taken to ensure that the number and distribution of missing data, both by month and by hour of the day, did not introduce significant biases into the analysis. Annual cumulative frequency distributions were constructed from the relative frequency distributions compiled for each month. Each individual month's data were included if they met the following screening criteria for completeness and unbiased distribution of missing data after data filling:

- The number of hourly dry-bulb temperature values for the month, after filling by interpolation, had to be at least 85% of the total hours for the month.
- The difference between the number of day and nighttime dry-bulb temperature observations had to be less than 60.

Although the nominal period of record selected for this analysis was 25 years (1990 to 2014 for most stations), some variation and gaps in observed data meant that some months' data were unusable because of incompleteness. Some months were also eliminated during additional quality control checks. A station's dry-bulb temperature design conditions were calculated only if there were data from at least 8 months that met the quality control and screening criteria from the period of record for each month of the year. For example, there had to be 8 months each of January, February, March, etc. for which data met the completeness screening criteria. These criteria were ascertained from results of RP-1171 (Hubbard et al. 2004) and were the same as used in calculating the design conditions in the 2001 to 2013 editions of the *ASHRAE Handbook—Fundamentals*.

Dew-point temperature, wet-bulb temperature, and enthalpy design conditions were calculated for a given month only if the number of dew-point, wet-bulb, or enthalpy values was greater than 85% of the minimum number of dry-bulb temperature values defined previously; wind speed and direction conditions were calculated for a given month only if the number of values was greater than 28.3% (i.e., one-third of 85%) the minimum number of dry-bulb temperature values. For example, a month of January was included in calculations if the number of dry-bulb temperature values exceeded 85% of 744 h, or 633 h. The month was included in calculation of dew-point temperature design conditions only if dew-point temperature was present for at least 85% of 633 h, or 538 h. The month was included in calculation of wind speed design conditions only if wind speed was present for at least 28.3% of 633 h, or 179 h.

Annual dry-bulb temperature extremes were calculated only for years that were 85% complete. At least 8 annual extremes were required to calculate the mean and standard deviation of extreme annual dry-bulb temperatures.

Daily minimum and maximum temperatures were calculated only for complete days; so were daily temperature ranges and mean coincident temperature ranges.

Details about quality checks and other steps taken during data processing to ensure results as free from error as possible are detailed in Roth (2017).

Differences from Previously Published Design Conditions

- Climatic design conditions in this chapter are generally similar to those in previous editions, because similar if not identical analysis procedures were used. There are some differences, however, owing to a more recent period of record (generally 1990-2014 versus 1982-2006). For example, when compared to the 2009 edition, 99.6% heating dry-bulb temperatures have increased by 0.05 K on average, and 0.4% cooling dry-bulb temperatures have increased by 0.08 K on average. Similar trends are observed for other design temperatures. The root mean square differences are 0.63 K for the 99.6% heating dry-bulb values and 0.36 K for 0.4% cooling dry-bulb. The increases noted here are generally consistent with the discussion in the section on Effects of Climate Change.
- Further details concerning differences between design conditions in the 2013, 2009, and 2005 editions are described in Thevenard (2009) and Thevenard and Gueymard (2013). Differences between the 2005 and the 2001 editions are described in Thevenard et al. (2005). Differences between the 1993 and previous editions are described in Colliver et al. (2000).

Applicability and Characteristics of Design Conditions

Climatic design values in this chapter represent different psychrometric conditions. Design data based on dry-bulb temperature represent peak occurrences of the sensible component of ambient outdoor conditions. Design values based on wet-bulb temperature are related to the enthalpy of the outdoor air. Conditions based on dew point relate to the peaks of the humidity ratio. The designer, engineer, or other user must decide which set(s) of conditions and probability of occurrence apply to the design situation under consideration. Additional sources of information on frequency and duration of extremes of temperature and humidity are provided in the section on Other Sources of Climatic Information. Further information is available from Harriman et al. (1999). This section discusses the intended use of design conditions in the order they appear in Table 1.

Annual Heating and Humidification Design Conditions. The month with the lowest mean dry-bulb temperature is used, for example, to determine the time of year where the maximum heating load occurs.

The 99.6 and 99.0% design conditions are often used in sizing heating equipment.

The humidification dew-point and mean coincident dry-bulb temperatures and humidity ratio provide information for cold-season humidification applications.

Wind design data provide information for estimating peak loads accounting for infiltration: extreme wind speeds for the coldest month, with the mean coincident dry-bulb temperature; and mean wind speed and direction coincident to the 99.6% design dry-bulb temperature.

Annual Cooling, Dehumidification, and Enthalpy Design Conditions. The month with the highest mean dry-bulb temperature is used, for example, to determine the time of year where the maximum sensible cooling load occurs, not taking into account solar loads.

The mean daily dry-bulb temperature range for the hottest month is the mean difference between the daily maximum and minimum temperatures during the hottest month and is calculated from the extremes of the hourly temperature observations. The true maximum and minimum temperatures for any day generally occur between hourly readings. Thus, the mean maximum and minimum temperatures calculated in this way are about 0.5 K less extreme than the mean daily extreme temperatures observed with maximum and minimum thermometers. This results in the true daily temperature range generally about 1 K greater than that calculated from hourly data. The mean daily dry-bulb temperature range is used in cooling load calculations.

The 0.4, 1.0, and 2.0% dry-bulb temperatures and mean coincident wet-bulb temperatures often represent conditions on hot,

Licensed for single user. © 2021 ASHRAE, Inc.

mostly sunny days. These are often used in sizing cooling equipment such as chillers or air-conditioning units.

Design conditions based on wet-bulb temperature represent extremes of the total sensible plus latent heat of outdoor air. This information is useful for design of cooling towers, evaporative coolers, and outdoor-air ventilation systems.

The mean wind speed and direction coincident with the 0.4% design dry-bulb temperature is used for estimating peak loads accounting for infiltration.

Design conditions based on dew-point temperatures are directly related to extremes of humidity ratio, which represent peak moisture loads from the weather. Extreme dew-point conditions may occur on days with moderate dry-bulb temperatures, resulting in high relative humidity. These values are especially useful for humidity control applications, such as desiccant cooling and dehumidification, cooling-based dehumidification, and outdoor-air ventilation systems. The values are also used as a check point when analyzing the behavior of cooling systems at part-load conditions, particularly when such systems are used for humidity control as a secondary function. Humidity ratio values are calculated from the corresponding dew-point temperature and the standard pressure at the location's elevation.

Annual enthalpy design conditions give the annual enthalpy for the cooling season; this is used for calculating cooling loads caused by infiltration and/or ventilation into buildings. Enthalpy represents the total heat content of air (the sum of its sensible and latent energies). Cooling loads can be calculated knowing the conditions of both the outdoor ambient and the building's interior air.

The extreme maximum wet-bulb temperature provides the highest wet-bulb temperature observed over the entire period of record and is the most extreme condition observed during the data record for evaporative processes such as cooling towers. For most locations, the extreme maximum wet-bulb value is significantly higher than the 0.4% wet-bulb (discussed previously) and should be used only for design of critical applications where an occasional short-duration capacity shortfall is not acceptable.

Extreme Annual Design Conditions. Extreme annual design wind speeds are used in designing smoke management systems.

The mean and standard deviation of the extreme annual maximum and minimum dry-bulb temperatures are used to calculate the probability of occurrence of very extreme conditions. These can be required for design of equipment to ensure continuous operation and serviceability regardless of whether the heating or cooling loads are being met. These values were calculated from extremes of hourly temperature observations. The true maximum and minimum temperatures for any day generally occur between hourly readings. Thus, the mean maximum and minimum temperatures calculated in this way are about 0.5 K less extreme than the mean daily extreme temperatures observed with maximum and minimum thermometers.

The 5-, 10-, 20- and 50-year return periods for maximum and minimum extreme dry-bulb temperature are also listed in the table. Return period (or recurrence interval) is defined as the reciprocal of the annual probability of occurrence. For instance, the 50-year return period maximum dry-bulb temperature has a probability of occurring or being exceeded of 2.0% (i.e., 1/50) each year. This statistic does not indicate how often the condition will occur in terms of the number of hours each year (as in the design conditions based on percentiles) but describes the probability of the condition occurring at all in any year. The following method can be used to estimate the return period (recurrence interval) of extreme temperatures:

$$T_n = M + IFs \tag{1}$$

where

T_n = n-year return period value of extreme dry-bulb temperature to be estimated, years

M = mean of annual extreme maximum or minimum dry-bulb temperatures, °C

s = standard deviation of annual extreme maximum or minimum dry-bulb temperatures, K

I = 1 if maximum dry-bulb temperatures are being considered

= –1 if minimum dry-bulb temperatures are being considered

$$F = -\frac{\sqrt{6}}{\pi}\left\{0.5772 + \ln\left[\ln\left(\frac{n}{n-1}\right)\right]\right\}$$

For example, the 50-year return period extreme maximum dry-bulb temperature estimated for Atlanta, GA, is 41.2°C (according to Table 1, M = 35.9°C, s = 2.0, and n = 50; I = 1). Similarly, the 50-year return period extreme minimum dry-bulb temperature for Atlanta, GA, is –16.1°C [M = –9.5°C, s = 2.6, and n = 50; I = –1]. The n-year return periods can be obtained for most stations using ASHRAE's Weather Data Viewer 6.0 (ASHRAE 2017), which is discussed in the section on Other Sources of Climatic Information.

New in 2017 are the parameters required to calculate the 5-, 10-, 20- and 50-year return periods for maximum and minimum extreme wet-bulb temperature. The maximum conditions in particular may be useful in determining very extreme wet-bulb temperatures during which evaporative systems may have to operate.

Calculation of the n-year return period is based on assumptions that annual maxima and minima are distributed according to the Gumbel (Type 1 Extreme Value) distribution and are fitted with the method of moments (Lowery and Nash 1970). The uncertainty or standard error using this method increases with standard deviation, value of return period, and decreasing length of the period of record. It can be significant. For instance, the standard error in the 50-year return period maximum dry-bulb temperature estimated at a location with a 12-year period of record can be 3 K or more. Thus, the uncertainties of return period values estimated in this way are greater for stations with fewer years of data than for stations with the complete period of record from 1990 to 2014.

Temperatures, Degree-Days, and Degree-Hours. Monthly average temperatures and standard deviation of daily average temperatures are calculated using the averages of the minimum and maximum temperatures for each complete day within the period analyzed. They are used to estimate heating and cooling degree-days to any base, as explained in the section on Estimation of Degree-Days.

Heating and cooling degree-days (base 10 or 18.3°C) are calculated as the sum of the differences between daily average temperatures and the base temperature. For example the number of **heating degree-days (HDD)** in the month is calculated as

$$\text{HDD} = \sum_{i=1}^{N} (T_{base} - \overline{T}_i)^+ \tag{2}$$

where N is the number of days in the month, T_{base} is the reference temperature to which the degree-days are calculated, and $\overline{T}_i$ is the mean daily temperature calculated by adding the maximum and minimum temperatures for the day, then dividing by 2. The + superscript indicates that only positive values of the bracketed quantity are taken into account in the sum. Similarly, monthly **cooling degree-days (CDD)** are calculated as

$$\text{CDD} = \sum_{i=1}^{N} (\overline{T}_i - T_{base})^+ \tag{3}$$

Degree-days are used in energy estimating methods, and to classify stations into climate zones for ASHRAE *Standard* 169.

Monthly Design Dry-Bulb and Mean Coincident Wet-Bulb Temperatures. These values provide design conditions for processes driven by dry-bulb air temperature. In particular, air-conditioning

Licensed for single user. © 2021 ASHRAE, Inc.

cooling loads are generally based on dry-bulb design conditions (plus clear-sky solar irradiance).

Monthly Design Wet-Bulb and Mean Coincident Dry-Bulb Temperatures. Wet-bulb design conditions are of use in analysis of evaporative coolers, cooling towers, and other equipment involving evaporative transfer. Note also that air wet-bulb temperature and enthalpy are closely related, so applications with large ventilation flow rates may have maximum cooling requirements under high wet-bulb conditions.

Mean Daily Temperature Range. Mean daily range values are computed using all days of the month, as opposed to coincident values that derive from design days. Mean daily range values have been published in previous Handbook editions and are included for completeness. Coincident daily range values should be used for generating design-day profiles.

Table 2 Approximate Astronomical Data for 21st Day of Each Month

Month	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec
Day of year	21	52	80	111	141	172	202	233	264	294	325	355
E_o, W/m^2	1410	1397	1378	1354	1334	1323	1324	1336	1357	1380	1400	1411
Equation of time (ET), min	–10.6	–14.0	–7.9	1.2	3.7	–1.3	–6.4	–3.6	6.9	15.5	13.8	2.2
Declination δ, degrees	–20.1	–11.2	–0.4	11.6	20.1	23.4	20.4	11.8	–0.2	–11.8	–20.4	–23.4

Clear-Sky Solar Irradiance. Clear-sky solar irradiance data are used in load calculation methods. **Beam normal irradiance** refers to solar radiation emanating directly from the solar disk and measured perpendicularly to the rays of the sun. **Diffuse horizontal irradiance** refers to solar radiation emanating from the sky dome, sun excluded, and measured on a horizontal surface. Because the beam and diffuse irradiances vary during the course of the day, current load calculation methods require their estimation at various times, which can be done with the method described in the section on Calculating Clear-Sky Solar Radiation. The method uses the clear-sky optical depths τ_b and τ_d, listed in Table 1 as *taub* and *taud*, respectively, as inputs. Clear-sky beam normal and diffuse horizontal irradiances at solar noon are also listed in Table 1 for convenience.

All-Sky Solar Radiation. All-sky solar radiation data are used in the design of solar energy systems (either thermal or photovoltaic). **Monthly average daily radiation on the horizontal** refers to average amount of solar radiation received on a horizontal surface during the course of a day, for the month under consideration. The **standard deviation of monthly average daily radiation on the horizontal** is the standard deviation of the previous monthly quantity, calculated over the period of record used for the Handbook, and is an indicator of the year-to-year variability of solar radiation.

2. CALCULATING CLEAR-SKY SOLAR RADIATION

Knowledge of clear-sky solar radiation at various times of year and day is required by several calculation methods for heat gains in HVAC loads and solar energy applications. The tables of climatic design conditions include the parameters required to calculate clear-sky beam and diffuse solar irradiances using the equations in the following section. The section on Transposition to Receiving Surfaces of Various Orientations explains how to use these values to calculate clear-sky solar radiation incident on arbitrary surfaces.

Note that in all equations in this section, *angles are expressed in degrees*. This includes the arguments appearing in trigonometric functions.

Solar Constant and Extraterrestrial Solar Radiation

The **solar constant E_{sc}** is defined as the intensity of solar radiation on a surface normal to the sun's rays, just beyond the earth's atmosphere, at the average earth-sun distance. One frequently used value is that proposed by the World Meteorological Organization in 1981, E_{sc} = 1367 W/m^2 (Iqbal 1983).

Because the earth's orbit is slightly elliptical, the **extraterrestrial radiant flux E_o** varies throughout the year, reaching a maximum of 1412 W/m^2 near the beginning of January, when the earth is closest to the sun (aphelion) and a minimum of 1322 W/m^2 near the beginning of July, when the earth is farthest from the sun (perihelion). Extraterrestrial solar irradiance incident on a surface normal to the sun's ray can be approximated with the following equation:

$$E_o = E_{sc}\left\{1 + 0.033\cos\left[360° \frac{(n-3)}{365}\right]\right\} \quad (4)$$

where n is the day of year (1 for January 1, 32 for February 1, etc.) and the argument inside the cosine is in degrees. Table 2 tabulates values of E_o for the 21st day of each month.

Table 3 Time Zones in United States and Canada

Time Zone Name	TZ (Hours ± UTC)	Local Standard Meridian Longitude (°E)
Newfoundland standard time	–3.5	–52.5
Atlantic standard time	–4	–60
Eastern standard time	–5	–75
Central standard time	–6	–90
Mountain standard time	–7	–105
Pacific standard time	–8	–120
Alaska standard time	–9	–135
Hawaii-Aleutian standard time	–10	–150

Equation of Time and Solar Time

The earth's orbital velocity also varies throughout the year, so **apparent solar time (AST)**, as determined by a solar time sundial, varies somewhat from the **mean time** kept by a clock running at a uniform rate. This variation is called the **equation of time (ET)** and is approximated by the following formula (Iqbal 1983):

$$\mathrm{ET} = 2.2918[0.0075 + 0.1868\cos(\Gamma) - 3.2077\sin(\Gamma) - 1.4615\cos(2\Gamma) - 4.089\sin(2\Gamma)] \quad (5)$$

with ET expressed in minutes and

$$\Gamma = 360° \frac{n-1}{365} \quad (6)$$

Table 2 tabulates the values of ET for the 21st day of each month.

The conversion between local standard time and solar time involves two steps: the equation of time is added to the local standard time, and then a longitude correction is added. This longitude correction is four minutes of time per degree difference between the **local (site) longitude** and the longitude of the **local standard meridian (LSM)** for that time zone; hence, AST is related to the **local standard time (LST)** as follows:

Licensed for single user. © 2021 ASHRAE, Inc.

$$AST = LST + ET/60 + (LON - LSM)/15 \quad (7)$$

where

AST = apparent solar time, decimal hours
LST = local standard time, decimal hours
ET = equation of time in minutes, from Table 2 or Equation (5)
LSM = longitude of local standard time meridian, °E of Greenwich (negative in western hemisphere)
LON = longitude of site, °E of Greenwich

Most standard meridians are found every 15° from 0° at Greenwich, U.K., with a few exceptions, such as the province of Newfoundland in Canada. Standard meridian longitude is related to time zone as follows:

$$LSM = 15TZ \quad (8)$$

where TZ is the time zone, expressed in hours ahead or behind **coordinated universal time (UTC)**. TZ is listed for each station on the CD-ROM accompanying this book. Table 3 lists time zones and standard time meridians for the United States and Canada.

If **daylight saving time** (DST) is to be used, rather than local standard time, an additional correction has to be performed. In most locales, local standard time can be obtained from daylight savings time by subtracting one hour:

$$LST = DST - 1 \quad (9)$$

where DST is in decimal hours.

Declination

Because the earth's equatorial plane is tilted at an angle of 23.45° to the orbital plane, the **solar declination** δ (the angle between the earth/sun line and the equatorial plane) varies throughout the year, as shown in Figure 2. This variation causes the changing seasons with their unequal periods of daylight and darkness. Declination can be obtained from astronomical or nautical almanacs; however, for most engineering applications, the following equation provides sufficient accuracy:

$$\delta = 23.45 \sin\left(360° \frac{n + 284}{365}\right) \quad (10)$$

where δ is in degrees and the argument inside the sine is also in degrees. Table 2 provides δ for the 21st day of each month.

Sun Position

The sun's position in the sky is conveniently expressed in terms of the solar altitude above the horizontal and the solar azimuth measured from the south (Figure 3). The solar altitude angle β is defined as the angle between the horizontal plane and a line emanating from the sun. Its value ranges from 0° when the sun is on the horizon, to 90° if the sun is directly overhead. Negative values correspond to night times. The solar azimuth angle ϕ is defined as angular displacement from south of the projection, on the horizontal plane, of the earth/sun line. By convention, it is counted positive for afternoon hours and negative for morning hours.

Solar altitude and azimuth angles, in turn, depend on the local latitude *L* (°N, negative in the southern hemisphere); the solar declination δ, which is a function of the date [see Table 2 or Equation

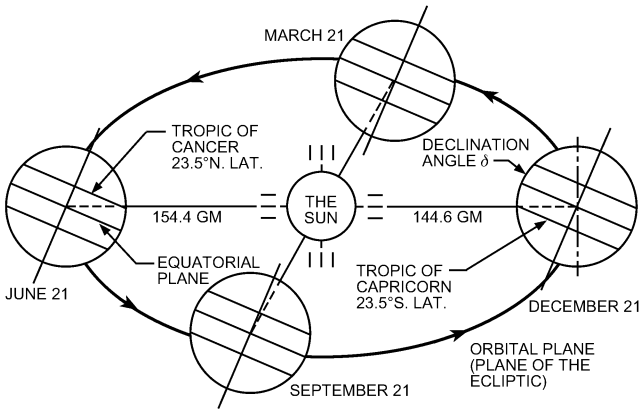

Fig. 2 Motion of Earth around Sun

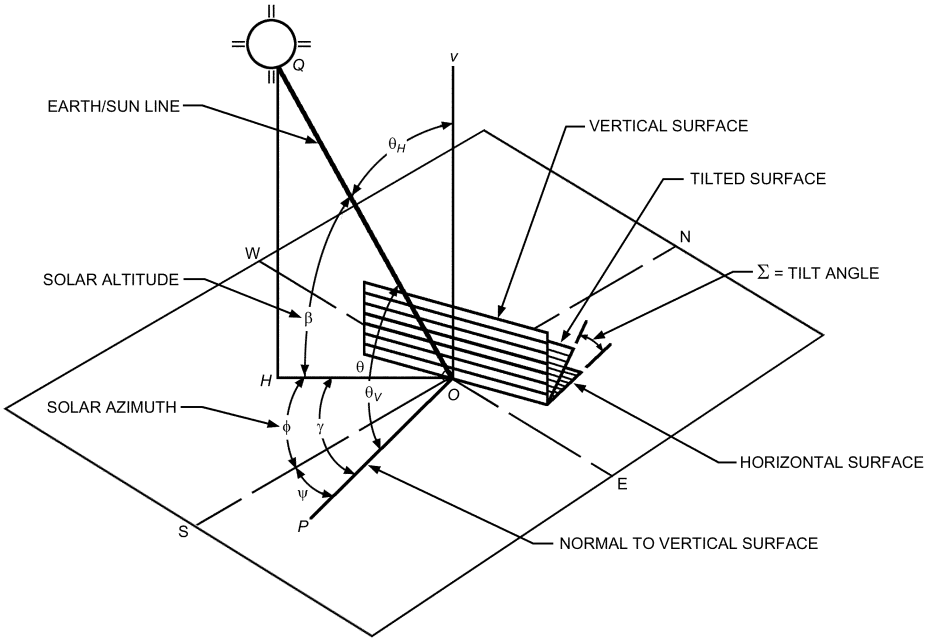

Fig. 3 Solar Angles for Vertical and Horizontal Surfaces

Licensed for single user. © 2021 ASHRAE, Inc.

(10)]; and the hour angle H, defined as the angular displacement of the sun east or west of the local meridian caused by the rotation of the earth, and expressed in degrees as

$$H = 15(\text{AST} - 12) \quad (11)$$

where AST is the apparent solar time [Equation (7)]. H is zero at solar noon, positive in the afternoon, and negative in the morning.

Equation (12) relates the solar altitude angle β to L, δ, and H:

$$\sin\beta = \cos L \cos\delta \cos H + \sin L \sin\delta \quad (12)$$

Note that at solar noon, $H = 0$ and the sun reaches its maximum altitude in the sky:

$$\beta_{max} = 90° - |L - \delta| \quad (13)$$

The azimuth angle ϕ is uniquely determined by its sine and cosine, given in Equations (14) and (15):

$$\sin\phi = \sin H \cos\delta / \cos\beta \quad (14)$$

$$\cos\phi = (\cos H \cos\delta \sin L - \sin\delta \cos L)/\cos\beta \quad (15)$$

Example 1. Calculate the position of the sun in Atlanta, GA, for July 21 at noon solar time.

Solution: From Table 1, Atlanta is at latitude $L = 33.64°$N. From Table 2 or Equation (10), declination $\delta = 20.44°$.

Solar altitude is given by Equation (13):

$$\beta = 90 - |33.64 - 20.44| = 76.80°$$

At solar noon, the sun is due south, so the azimuth angle ϕ is simply 0°.

Example 2. Perform the same calculation as in Example 1, but for 3:00 PM eastern daylight saving time.

Solution: Compared to Example 1, a few extra steps are required to calculate AST. From Table 1, for Atlanta, LON = 84.43°W = −84.43°E and TZ = −5.00. Also, from Table 1 or Equation (5), ET = −6.4 min. Then, from Equation (8):

$$\text{LSM} = 15(-5.00) = -75°$$

Because 3 PM daylight saving time is 2 PM standard time, or hour 14, Equation (7) leads to

$$\text{AST} = 14 - 6.4/60 + [(-84.43) - (-75)]/15 = 13.27 \text{ h}$$

Then, from Equation (11):

$$H = 15(13.27 - 12) = 18.97°$$

Solar altitude is given by Equation (12), using the same latitude and declination as in Example 1:

$$\sin\beta = \cos(33.64°)\cos(20.44°)\cos(18.97°) + \sin(33.64°)\sin(20.44°) = 0.931$$

Therefore, $\beta = 68.62°$.

Solar azimuth is obtained through Equations (14) and (15):

$$\sin\phi = \sin(18.97°)\cos(20.44°)/\cos(68.62°) = 0.836$$

$$\cos\phi = [\cos(18.97°)\cos(20.44°)\sin(33.64°) - \sin(20.44°)\cos(33.64°)]/\cos(68.62°) = 0.549$$

Therefore, $\phi = 56.69°$.

Air Mass

The relative air mass m is the ratio of the mass of atmosphere in the actual earth/sun path to the mass that would exist if the sun were directly overhead. Air mass is solely a function of solar altitude β and is obtained from (Kasten and Young 1989)

$$m = 1/[\sin\beta + 0.50572(6.07995 + \beta)^{-1.6364}] \quad (16)$$

where β is expressed in degrees.

Clear-Sky Solar Radiation

Solar radiation on a clear day is defined by its beam (direct) and diffuse components. The direct component represents the part of solar radiation emanating directly from the solar disc, whereas the diffuse component accounts for radiation emanating from the rest of the sky. These two components are calculated as

$$E_b = E_o \exp[-\tau_b m^{ab}] \quad (17)$$

$$E_d = E_o \exp[-\tau_d m^{ad}] \quad (18)$$

where

E_b = beam normal irradiance (measured perpendicularly to rays of the sun)
E_d = diffuse horizontal irradiance (measured on horizontal surface)
E_o = extraterrestrial normal irradiance [Equation (4) or Table 2]
m = air mass [Equation (16)]
τ_b and τ_d = beam and diffuse optical depths (τ_b and τ_d are more correctly termed pseudo-optical depths, because optical depth refers to an air mass coefficient without exponentiation; "optical depth" is used here for convenience.)
ab and ad = beam and diffuse air mass exponents

Values of τ_b and τ_d are location-specific, and vary during the year. They embody the dependence of clear-sky solar radiation on local conditions, such as elevation, precipitable water, aerosols, ozone, and surface reflectance. In previous editions, their average values were determined through ASHRAE research projects RP-1453 (Thevenard 2009) and RP-1613 (Thevenard and Gueymard 2013). For this edition, the results are from RP-1699 (Roth 2017), and are tabulated for the 21st day of each month for all the locations in the tables of climatic design conditions. Values for other days of the year should be found by interpolation.

Air mass exponents ab and ad are correlated to τ_b and τ_d through the following empirical relationships:

$$ab = 1.454 - 0.406\,\tau_b - 0.268\,\tau_d + 0.021\,\tau_b\tau_d \quad (19)$$

$$ad = 0.507 + 0.205\,\tau_b - 0.080\,\tau_d - 0.190\,\tau_b\tau_d \quad (20)$$

Equations (17) to (20) describe a simple parameterization of a sophisticated broadband radiation model and provide accurate predictions of E_b and E_d, even at sites where the atmosphere is very hazy or humid most of the time.

Example 3. Calculate clear-sky beam and diffuse solar irradiance in Atlanta, GA, for July 21 at noon solar time. Note that Table 1 already lists clear-sky beam and diffuse solar irradiance for solar noon. Calculations are shown here to illustrate the application of the method.

Solution: From Example 1, at solar noon on July 21 in Atlanta solar altitude is $\beta = 76.80°$. From Equation (16):

$$m = 1/[\sin(76.80°) + 0.50572(6.07995 + 76.80)^{-1.6364}] = 1.027$$

From Table 1, the beam and diffuse optical depths for Atlanta in July are $\tau_b = 0.515$ and $\tau_d = 2.066$. From Table 2 or Equation (4), normal extraterrestrial irradiance on July 21 is $E_o = 1324$ W/m^2. Then, from Equations (19) and (20)

$$ab = 1.454 - 0.406 \times 0.515 - 0.268 \times 2.066 + 0.021 \times 0.515 \times 2.066 = 0.714$$

$$ad = 0.507 + 0.205 \times 0.515 - 0.080 \times 2.066 - 0.190 \times 0.515 \times 2.066 = 0.245$$

and from Equations (17) and (18),

$$E_b = 1324 \exp(-0.515 \times 1.027^{0.714}) = 784 \text{ W/m}^2$$

$$E_d = 1324 \exp(-2.066 \times 1.027^{0.245}) = 166 \text{ W/m}^2$$

These are the values listed for $Eb_{n,noon}$ and $Edh_{,noon}$ in Table 1.

Licensed for single user. © 2021 ASHRAE, Inc.

Example 4. Perform the same calculation as in Example 3, but for 3 PM eastern daylight saving time.

Solution: This is the same calculation as in the solution of Example 3, but using the solar altitude $\beta = 68.62°$ calculated in Example 2 (*ab* and *ad* are unchanged from Example 3):

$$m = 1/[\sin(68.62°) + 0.50572(6.07995 + 68.62)^{-1.6364}] = 1.073$$

$$E_b = 1324 \exp(-0.515 \times 1.073^{0.714}) = 770 \text{ W/m}^2$$

$$E_d = 1324 \exp(-2.066 \times 1.073^{0.245}) = 162 \text{ W/m}^2$$

3. TRANSPOSITION TO RECEIVING SURFACES OF VARIOUS ORIENTATIONS

Calculations developed in the previous section are chiefly concerned with estimating clear-sky solar irradiance either normal to the rays of the sun (direct beam) or on a horizontal surface (diffuse). However, in many circumstances, calculation of clear-sky solar irradiance is required on surfaces of arbitrary orientations. Receiving surfaces can be vertical (e.g., walls and windows) or tilted (e.g., skylights or active solar devices). This section describes **transposition models** that enable calculating solar irradiance on any surface, knowing beam normal and diffuse horizontal irradiance.

Table 4 Surface Orientations and Azimuths, Measured from South

Orientation	N	NE	E	SE	S	SW	W	NW
Surface azimuth ψ	180°	−135°	−90°	−45°	0	45°	90°	135°

Solar Angles Related to Receiving Surfaces

The orientation of a receiving surface is best characterized by its tilt angle and its azimuth, shown in Figure 3. The tilt angle Σ (also called **slope**) is the angle between the surface and the horizontal plane. Its value lies between 0 and 180°. Most often, slopes are between 0° (horizontal) and 90° (vertical). Values above 90° correspond to surfaces facing the ground. The surface azimuth ψ is defined as the displacement from south of the projection, on the horizontal plane, of the normal to the surface. Surfaces that face west have a positive surface azimuth; those that face east have a negative surface azimuth. Surface azimuths for common orientations are summarized in Table 4. Note that, in this chapter, surface azimuth is defined as relative to south in both the northern and southern hemispheres. Other presentations and software use relative-to-north or relative-to-equator; care is required.

The surface-solar azimuth angle γ is defined as the angular difference between the solar azimuth ϕ and the surface azimuth ψ:

$$\gamma = \phi - \psi \tag{21}$$

Values of γ greater than 90° or less than –90° indicate that the surface is in the shade.

Finally, the angle between the line normal to the irradiated surface and the earth-sun line is called the angle of incidence θ. It is important in fenestration, load calculations, and solar technology because it affects the intensity of the direct component of solar radiation striking the surface and the surface's ability to absorb, transmit, or reflect the sun's rays. Its value is given by

$$\cos\theta = \cos\beta\cos\gamma\sin\Sigma + \sin\beta\cos\Sigma \tag{22}$$

Note that for vertical surfaces ($\Sigma = 90°$) Equation (22) simplifies to

$$\cos\theta = \cos\beta\cos\gamma \tag{23}$$

whereas for horizontal surfaces ($\Sigma = 0°$) it simplifies to

$$\theta = 90 - \beta \tag{24}$$

Example 5. For Atlanta, GA, on July 21 at 3 PM eastern daylight saving time, find the angle of incidence at a vertical widow facing 60° west of south.

Solution: The azimuth of the receiving surface is $\psi = +60°$. According to Example 2, solar azimuth angle is $\phi = 56.69°$. Then, Equation (21) gives the surface-solar azimuth angle as

$$\gamma = 56.69° - 60° = -3.31°$$

Still from Example 2, solar altitude angle is $\beta = 68.62°$. Equation (23) leads to

$$\cos\theta = \cos(68.62°)\cos(-3.31°) = 0.364$$

Therefore, $\theta = 68.66°$.

Example 6. For the same conditions as in Example 5, find the angle of incidence at a skylight tilted at 30° and facing 60° west of south.

Solution: The azimuth of the receiving surface is still $\psi = +60°$, but its slope is $\Sigma = 30°$. Other angles are unchanged from Example 5. Equation (22) now applies:

$$\cos\theta = \cos(68.62°)\cos(-3.31°)\sin(30°) + \sin(68.62°)\cos(30°) = 0.988$$

which leads to $\theta = 8.74°$.

Calculation of Clear-Sky Solar Irradiance Incident On Receiving Surface

Total clear-sky irradiance E_t reaching the receiving surface is the sum of three components: the beam component $E_{t,b}$ originating from the solar disc; the diffuse component $E_{t,d}$, originating from the sky dome; and the ground-reflected component $E_{t,r}$ originating from the ground in front of the receiving surface. Thus,

$$E_t = E_{t,b} + E_{t,d} + E_{t,r} \tag{25}$$

Only a simple method for computing all the factors on the right side of Equation (25) is presented here. More elaborate methods, particularly with regard to the calculating the diffuse component, can be found in Gueymard (1987) and Perez et al. (1990).

Beam Component. The beam component is obtained from a straightforward geometric relationship:

$$E_{t,b} = E_b \cos\theta \tag{26}$$

where θ is the angle of incidence. This relationship is valid only when $\cos\theta > 0$; otherwise, $E_{t,b} = 0$.

Diffuse Component. The diffuse component is more difficult to estimate because of the anisotropic nature of diffuse radiation: some parts of the sky, such as the circumsolar disc or the horizon, tend to be brighter than the rest of the sky, which makes the development of a simplified model challenging. For vertical surfaces, Stephenson (1965) and Threlkeld (1963) showed that the ratio Y of clear-sky diffuse irradiance on a vertical surface to clear-sky diffuse irradiance on the horizontal is a simple function of the angle of incidence θ:

$$E_{t,d} = E_d Y \tag{27}$$

with

$$Y = \max(0.45,\ 0.55 + 0.437\cos\theta + 0.313\ \cos^2\theta) \tag{28}$$

For a nonvertical surface with slope Σ, the following simplified relationships are sufficient for most applications described in this volume:

$$E_{t,d} = E_d(Y\sin\Sigma + \cos\Sigma) \qquad \text{if } \Sigma \le 90° \tag{29}$$

$$E_{t,d} = E_d Y\sin\Sigma \qquad \text{if } \Sigma > 90° \tag{30}$$

Licensed for single user. © 2021 ASHRAE, Inc.

where Y is calculated for a *vertical surface* having the same azimuth as the receiving surface considered.

Note that Equations (27) to (30) are appropriate for clear-sky conditions, but should not be used for cloudy skies.

Ground-Reflected Component. Ground-reflected irradiance for surfaces of all orientations is given by

$$E_{t,r} = (E_b \sin\beta + E_d)\rho_g \frac{1 - \cos\Sigma}{2} \quad (31)$$

where ρ_g is ground reflectance, often taken to be 0.2 for a typical mixture of ground surfaces. Table 5 provides estimates of ρ_g for other surfaces, including in the presence of snow.

Example 7. Find the direct, diffuse and ground-reflected components of clear-sky solar irradiance on the window in Example 5.

Solution: Clear-sky beam normal irradiance E_b and diffuse horizontal irradiance E_d were calculated in Example 4 as E_b = 770 W/m^2 and E_d = 162 W/m^2. Example 2 provided the solar altitude as $\beta = 68.62°$ and Example 5 provided the angle of incidence as $\theta = 68.66°$. The surface slope is $\Sigma = 90°$, and ground reflectance is assumed to be 0.2. Substituting these values into Equations (26), (27), (28), and (31) leads to

$$E_{t,b} = 770 \cos(68.66°) = 280 \text{ W/m}^2$$

$$Y = \max[0.45, 0.55 + 0.437 \cos(68.66°) + 0.313 \cos^2(68.66°)] = 0.750$$

$$E_{t,d} = 162 \times 0.750 = 121 \text{ W/m}^2$$

$$E_{t,r} = [770 \sin(68.62°) + 162]0.2 \frac{1 - \cos(90°)}{2} = 87.9 \text{ W/m}^2$$

Example 8. Find the direct, diffuse and ground-reflected components of clear-sky solar irradiance on the skylight in Example 6.

Solution: This example uses the same values as Example 7, except that the surface slope is $\Sigma = 30°$ and the angle of incidence, calculated in Example 6, is $\theta = 8.74°$. The clear-sky irradiance components are then calculated from Equations (26), (29) and (31); the ratio Y is calculated for a *vertical* surface having the same azimuth as the receiving surface, so the value calculated in Example 7 is unchanged.

$$E_{t,b} = 770 \cos(8.74°) = 761 \text{ W/m}^2$$

$$E_{t,d} = 162[0.750 \sin(30°) + \cos(30°)] = 201 \text{ W/m}^2$$

$$E_{t,r} = [770 \sin(68.62°) + 162]0.2 \frac{1 - \cos(30°)}{2} = 11.8 \text{ W/m}^2$$

4. GENERATING DESIGN-DAY DATA

This section provides procedures for generating 24 h temperature data sequences suitable as input to many HVAC analysis methods, including the radiant time series (RTS) cooling load calculation procedure described in Chapter 18.

Temperatures. Table 6 gives a normalized daily temperature profile in fractions of daily temperature range. Recent research projects RP-1363 (Hedrick 2009) and RP-1453 (Thevenard 2009) have shown that this profile is representative of both dry-bulb and wet-bulb temperature variation on typical design days. To calculate hourly temperatures, subtract the Table 6 fraction of the dry- or wet-bulb daily range from the dry- or wet-bulb design temperature (limiting by saturation in the case of the wet-bulb). This procedure is applicable to annual or monthly data and is shown in Example 9. Table 7 specifies the input values to be used for generating several design-day types.

Because daily temperature variation is driven by heat from the sun, the profile in Table 6 is, strictly speaking, specified in terms of solar time. Typical HVAC calculations (e.g., hourly cooling loads) are performed in local time, reflecting building operation schedules. The difference between local and solar time can easily be 1 or 2 h, depending on site longitude and whether daylight saving time is in effect. This difference can be included by accessing the temperature profile using apparent solar time (AST) calculated with Equation (7), as shown in Example 9.

Table 5 Ground Reflectance of Foreground Surfaces

Foreground Surface	Reflectance
Water (near normal incidences)	0.07
Coniferous forest (winter)	0.07
Asphalt, new	0.05
weathered	0.10
Bituminous and gravel roof	0.13
Dry bare ground	0.2
Weathered concrete	0.2 to 0.3
Green grass	0.26
Dry grassland	0.2 to 0.3
Desert sand	0.4
Light building surfaces	0.6
Snow-covered surfaces:	
Typical city center	0.2
Typical urban site	0.4
Typical rural site	0.5
Isolated rural site	0.7

Source: Adapted from Thevenard and Haddad (2006).

Additional Moist-Air Properties. Once hourly dry-bulb and wet-bulb temperatures are known, additional moist air properties (e.g., dew-point temperature, humidity ratio, enthalpy) can be derived using the psychrometric chart, equations in Chapter 1, or psychrometric software.

Example 9. Deriving Hourly Design-Day Temperatures. Calculate hourly temperatures for Atlanta, GA, for a July dry-bulb design day using the 5% design conditions.

Solution: From Table 1, the July 5% dry-bulb design conditions for Atlanta are DB = 33.1°C and MCWB = 23.5°C. Daily range values are MCDBR = 11.2°C and MCWBR = 3.4°C. Daylight saving time is in effect for Atlanta in July. Apparent solar time (AST) for hour 1 local daylight saving time (LDT) is –0.73. The nearest hour to the AST is 23, yielding a Table 6 profile value of 0.75. Then $t_{db,1} = 33.1 - 0.75 \times 11.2 = 24.7$°C. Similarly, $t_{wb,1} = 23.5 - 0.75 \times 3.4 = 21.0$°C. With psychrometric formulas, derive $t_{dp,1} = 19.3$°C. Table 8 shows results of this procedure for all 24 h.

5. ESTIMATION OF DEGREE-DAYS

Monthly Degree-Days

The tables of climatic design conditions in this chapter list heating and cooling degree-days (bases 10 and 18.3°C). Although 10 and 18.3°C represent the most commonly used bases for the calculation of degree-days, calculation to other bases may be necessary. With that goal in mind, the tables also provide two parameters (monthly average temperature T, and standard deviation of daily average temperature s_d) that enable estimation of degree-days to any base with reasonable accuracy.

The calculation method was established by Schoenau and Kehrig (1990). Heating degree days HDD_b to base T_b are expressed as

$$HDD_b = Ns_d[Z_b F(Z_b) + f(Z_b)] \quad (32)$$

where N is the number of days in the month and Z_b is the difference between monthly average temperature $\bar{T}$ and base temperature T_b, normalized by the standard deviation of the daily average temperature s_d:

Licensed for single user. © 2021 ASHRAE, Inc.

$$Z_b = \frac{T_b - \bar{T}}{s_d} \quad (33)$$

Function f is the normal (Gaussian) probability density function with mean 0 and standard deviation 1, and function F is the equivalent cumulative normal probability function:

$$f(Z) = \frac{1}{\sqrt{2\pi}} \exp\left(\frac{-Z^2}{2}\right) \quad (34)$$

Table 6 Fraction of Daily Temperature Range

Time, h	Fraction	Time, h	Fraction	Time, h	Fraction
1	0.88	9	0.55	17	0.14
2	0.92	10	0.38	18	0.24
3	0.95	11	0.23	19	0.39
4	0.98	12	0.13	20	0.50
5	1.00	13	0.05	21	0.59
6	0.98	14	0.00	22	0.68
7	0.91	15	0.00	23	0.75
8	0.74	16	0.06	24	0.82

Table 7 Input Sources for Design-Day Generation

Design Day Type	Design Conditions	Daily Ranges	Limits
Dry-bulb			
Annual	0.4, 1, or 2% annual cooling DB/MCWB	Hottest month 5% DB MCDBR/MCWBR	Hourly wet-bulb temp. = min(dry-bulb temp., wet-bulb temp.)
Monthly	0.4, 2, 5, or 10% DB/MCWB for month	5% DB MCDBR/MCWBR for month	
Wet-bulb			
Annual	0.4, 1, or 2% annual cooling WB/MCDB	Hottest month 5% WB MCDBR/MCWBR	Hourly dry-bulb temp. = max(dry-bulb temp., wet-bulb temp.)
Monthly	0.4, 2, 5, or 10% WB/MCDB for month	5% WB MCDBR/MCWBR for month	

Table 8 Derived Hourly Temperatures for Atlanta, GA for July for 5% Design Conditions, °C

Hour (LDT)	t_{db}	t_{wb}	t_{dp}	Hour (LDT)	t_{db}	t_{wb}	t_{dp}
1	24.7	21.0	19.3	13	30.5	22.7	19.4
2	23.9	20.7	19.3	14	31.6	23.1	19.5
3	23.2	20.5	19.3	15	32.5	23.3	19.5
4	22.8	20.4	19.3	16	33.1	23.5	19.5
5	22.5	20.3	19.3	17	33.1	23.5	19.5
6	22.1	20.2	19.3	18	32.4	23.3	19.5
7	21.9	20.1	19.3	19	31.5	23.0	19.5
8	22.1	20.2	19.3	20	30.4	22.7	19.4
9	22.9	20.4	19.3	21	28.7	22.2	19.4
10	24.8	21.0	19.3	22	27.5	21.8	19.3
11	26.9	21.6	19.3	23	26.5	21.5	19.3
12	28.8	22.2	19.4	24	25.5	21.2	19.3

LDT = Local daylight saving time.

$$F(Z) = \int_{-\infty}^{Z} f(z)dz \quad (35)$$

Both f and F are readily available as built-in functions in many scientific calculators or spreadsheet programs, so their manual calculation is rarely warranted.

Cooling degree days CDD_b to base T_b are calculated by the same equation:

$$CDD_b = Ns_d[Z_b F(Z_b) + f(Z_b)] \quad (36)$$

except that Z_b is now expressed as

$$Z_b = \frac{\bar{T} - T_b}{s_d} \quad (37)$$

Alternative Equations. The following formulas from ISO *Standard* 15927-6 give results very similar to Equations (32) and (36) but are somewhat simpler:

$$HDD_b = \frac{N(T_b - \bar{T})}{1 - \exp(-\sqrt{2\pi}(T_b - \bar{T})/s_d)} \quad (38)$$

$$CDD_b = \frac{N(\bar{T} - T_b)}{1 - \exp(-\sqrt{2\pi}(\bar{T} - T_b)/s_d)} \quad (39)$$

When $\bar{T} = T_b$, the right-hand side of these equations become $Ns_d/\sqrt{2\pi}$.

Annual Degree-Days

Annual degree-days are simply the sum of monthly degree days over the twelve months of the year.

Example 10. Calculate heating and cooling degree-days (base 15°C) for Atlanta for the month of October.

Solution: For October in Atlanta, Table 1 provides T = 17.5°Cand s_d = 3.93°C. For heating degree-days, Equation (33) provides Z_b = (15 – 17.5)/3.93 = –0.636. From a scientific calculator or a spreadsheet program $f(Z_b)$ = 0.326, and $F(Z_b)$ = 0.262. Equation (32) then gives

$$HDD_{15} = 31 \times 3.93[-0.636 \times 0.262 + 0.326] = 19.4°C\text{-day}.$$

For cooling degree-days, Z_b = 0.636. Note that $f(-Z_b) = f(Z_b)$ and $F(-Z_b) = 1 - F(Z_b)$, hence

$$f(Z_b) = 0.326 \quad \text{and} \quad F(Z_b) = 0.738$$

and

$$CDD_{15} = 31 \times 3.93(0.636 \times 0.737 + 0.326) = 96.9°C\text{-day}.)$$

For most stations, the monthly degree-days calculated with this method are within 5°C-day of the observed values.

6. REPRESENTATIVENESS OF DATA AND SOURCES OF UNCERTAINTY

Representativeness of Data

The climatic design information in this chapter was obtained by direct analysis of observations from the indicated locations. Design values reflect an estimate of the cumulative frequency of occurrence of the weather conditions at the recording station, either for single or jointly occurring elements, for several years into the future. Several sources of uncertainty affect the accuracy of using the design conditions to represent other locations or periods.

The most important of these factors is spatial representativeness. Most of the observed data for which design conditions were calcu-

Licensed for single user. © 2021 ASHRAE, Inc.

lated were collected from airport observing sites, the majority of which are flat, grassy, open areas, away from buildings and trees or other local influences. Temperatures recorded in these areas may be significantly different from built-up areas where the design conditions are being applied. For example, the maximum urban heat island intensity may be 10 K or more (Oke 1987), although intraurban variability is typically quite large. Urban microclimate is affected by the three-dimensional density of building construction, usually represented by the ratio of building height to street width (H/W); by type and extent of plant cover; and by anthropogenic heat emissions from buildings and vehicles. Significant variations can also occur with changes in local elevation, even if elevations differ by a few hundred metres, or in the vicinity of large bodies of water. It should be emphasized that such variations are not constant in time: intraurban differences in temperature and humidity fluctuate not only in predictable diurnal patterns, but also in response to changes in synoptic conditions and wind direction. Urban heat islands, for example, are typically prominent on clear nights with little or no wind, and are weaker or nonexistent in windy conditions and during daytime. Therefore, judgment must always be used in assessing the representativeness of the design conditions. Consult an applied climatologist regarding estimating design conditions for locations not listed in this chapter. For online references to applied climatologists in the United States, see wcdirectory.ametsoc.org/certified-consulting-meteorologists; in Canada, consult cmos.ca/client/roster/clientRosterView.html?clientRosterId=190. Also, GIS-compatible files (KML format) are provided as a special feature in ASHRAE Handbook Online. This allows use of the data in a GIS environment such as Google Earth or ArcGIS, which provides capabilities to overlay various layers of information such as elevation, land use, and bodies of water. This type of information can greatly assist in determining the most representative location to use for an application.

Depending on a site's specific geographic location and setting (e.g., proximity to large body of water or hills), the data in this chapter for the nearest weather station may not be representative of the actual climate experienced at the project site. In these instances, it may be beneficial to obtain climate data using procedures developed by ASHRAE research project RP-1561 (Qiu et al. 2016). The methodologies provide a protocol for using state-of-the-art mesoscale modeling techniques to derive meteorological conditions specific to the study area. The research project included the methodology based on the Weather Research and Forecasting (WRF) model designed to develop site-specific climate data where standard weather stations are unavailable or not representative of site conditions. The methodology was evaluated by using observations in various geographic regions, including coastal, mountain valley, mountain plateau, and major cities. A simplified procedure was developed; it is freely available at klimaat.github.io/emspy/.

The underlying data also depend on the method of observation. During the 1990s, most data gathering in the United States and Canada was converted to automated systems designated either an automated surface observation system (ASOS) or an automated weather observing system (AWOS). This change improved completeness and consistency of available data. However, changes have resulted from the inherent differences in type of instrumentation, instrumentation location, and processing procedures between the prior manual systems and ASOS. These effects were investigated in ASHRAE research project RP-1226 (Belcher and DeGaetano 2004). Comparison of one-year ASOS and manual records revealed some biases in dry-bulb temperature, dew-point temperature, and wind speed. These biases are judged to be negligible for HVAC engineering purposes; the tabulated design conditions in this chapter were derived from mixed automated and manual data as available. Changes in the location of the observing instruments often have a larger effect than changes in instrumentation. On the other hand, ASOS measurements of sky coverage and ceiling height differ markedly from manual observations and are incompatible with solar radiation models used in energy simulation software. An updated solar model, compatible with ASOS data, was developed as part of RP-1226. The ASOS-based model was found less accurate than models based on manually observed data when compared to measured solar radiation.

Weather conditions vary from year to year and, to some extent, from decade to decade because of the inherent variability of climate. Similarly, values representing design conditions vary depending on the period of record used in the analysis. Thus, because of short-term climatic variability, there is always some uncertainty in using design conditions from one period to represent another period. Typically, values of design dry-bulb temperature vary less than 1 K from decade to decade, but larger variations can occur. Differing periods used in the analysis can lead to differences in design conditions between nearby locations at similar elevations. Design conditions may show trends in areas of increasing urbanization or other regions experiencing extensive changes to land use. Longer-term climatic change brought by human or natural causes may also introduce trends into design conditions. This is discussed further in the section on Effects of Climate Change.

Table 9 Locations Representing Various Climate Types

Cold Snow Forest	Dry	Warm Rainy	Tropical Rainy
Portland, ME	Amarillo, TX	Huntsville, AL	Key West, FL
Grand Island, NE	Bakersfield, CA	Wilmington, NC	West Palm Beach, FL
Minot, ND	Sacramento, CA	Portland, OR	
Indianapolis, IN	Phoenix, AZ	Quillayute, WA	

Wind speed and direction are very sensitive to local exposure features such as terrain and surface cover. The original wind data used to calculate the wind speed and direction design conditions in Table 1 are often representative of a flat, open exposure, such as at airports. Wind engineering methods, as described in Chapter 24, can be used to account for exposure differences between airport and building sites. This is a complex procedure, best undertaken by an experienced applied climatologist or wind engineer with knowledge of the exposure of the observing and building sites and surrounding regions.

Uncertainty from Variation in Length of Record

ASHRAE research project RP-1171 (Hubbard et al. 2004) investigated the uncertainty associated with the climatic design conditions in the 2001 *ASHRAE Handbook—Fundamentals*. The main objectives were to determine how many years are needed to calculate reliable design values and to look at the frequency and duration of episodes exceeding the design values.

Design temperatures in the 1997 and 2001 editions were calculated for locations for which there were at least 8 years of sufficient data; the criterion for using 8 years was based on unpublished work by TC 4.2. RP-1171 analyzed data records from 14 U.S. locations (Table 9) representing four different climate types. The dry-bulb temperatures corresponding to the five annual percentile design temperatures (99.6, 99, 0.4, 1, and 2%) from the 33-year period 1961-1993 (period used for the 2001 edition's U.S. stations) were calculated for each location. The temperatures corresponding to the same percentiles for each contiguous subperiod ranging from 1 to 33 years in length was calculated, and the standard deviation of the differences between the resulting design temperature from each subperiod and the entire 33-year period was calculated. For instance, for a 10-year period, the dry-bulb values corresponding to each of the 23 subperiods 1961-1970, 1962-1971, … 1984-1993 were calculated and the standard deviation of differences with the dry-bulb value for the same percentile from the 33-year period calculated. The standard deviation

Licensed for single user. © 2021 ASHRAE, Inc.

values represent a measure of uncertainty of the design temperatures relative to the design temperature for the entire period of record.

The results for the five annual percentiles are summarized in Figures 4A to 4E, each of which shows how the uncertainty (the average standard deviation for each of the locations in each climate type) varies with length of period.

To the degree that the differences used to calculate the standard deviations are distributed normally, the short-period design temperatures can be expected to lie within one standard deviation of the long-term design temperature 68% of the time. For example, from Figure 4A, the uncertainty for the cold snow forest for a 1-year period is 3.6 K. This can be interpreted that the probability is 68% that the difference in a 99.6% dry-bulb in any given year will be within 3.6 K of the long-term 99.6% dry-bulb. Similarly, there is a 68% probability that the 99.6% dry-bulb from any 10-year period will be within 1 K of the long-term value for a location of the cold snow forest climate type.

The uncertainty for the cold season is higher than for the warm season. For example, the uncertainty for the 99.6% dry-bulb for a 10-year period ranges from 0.6 to 1.0 K for the five climate types, whereas the uncertainty for the 0.4% dry-bulb for a 10-year period ranges from 0.4 to 0.6 K.

A variety of other general characteristics of uncertainty are evident from an inspection of Figure 4. For example, the highest uncertainty of any climate type for a 10-year period is 1.1 K for the cold snow forest 99% dry-bulb case. The smallest uncertainty is 0.2 K for the tropical rainy 1% and 2% dry-bulb cases.

Based on these results, it was concluded that using a minimum of 8 years of data would provide reliable (within ±1 K) climatic design calculations for most stations.

Effects of Climate Change

The evidence is unequivocal that the climate system is warming globally (IPCC 2007). The most frequently observed effects relate to increases in average, and to some degree, extreme temperatures.

This is partly shown by the results of an analysis of design conditions conducted as part of calculating the values for the 2009 edition of this chapter (Thevenard 2009). For 1274 observing sites worldwide with suitably complete data from 1977 to 2006, selected design conditions were compared between the period 1977-1986 and 1997-2006. The results, averaged over all locations, are as follows:

- The 99.6% annual dry-bulb temperature increased 1.52 K
- The 0.4% annual dry-bulb increased 0.79 K
- Annual dew point increased by 0.55 K
- Heating degree-days (base 18.3°C) decreased by 237°C-days
- Cooling degree-days (base 10°C) increased by 136°C-days

Although these results are consistent with general warming of the world climate system, there are other effects that undoubtedly contribute, such as increased urbanization around many of the observing sites (airports, typically). There was no attempt in the analysis to determine the reasons for the changes.

A more recent study by Thevenard and Shephard (2014), using stations used in the 2013 edition of this chapter, looked at trends for yearly average dry-bulb temperature and other quantities over the 1986 to 2010 period using statistical methods. The study showed that statistically significant increases in average dry-bulb temperature can be detected in only 19% of stations on an individual basis. However, trends become more apparent when stations are evaluated in groups. Stations were grouped in 5°×5° cells covering the globe. Of these cells, 44% showed an increase in average dry-bulb temperature, and 2% showed a decrease; 26% showed an increase in average dew-point temperature and 10% a decrease; finally, 34% showed an increase in average wet-bulb temperature, and 5% showed a decrease. Geographically, increases in average dry-bulb temperature were most visible throughout Europe, in China and southeast Asia, the eastern United States, and southern Australia, and are typically in the range of 0.2 to 0.6 K per decade. Northern locations exhibited higher positive trends (above 1 K per decade). Dew-point temperature increases were most visible in eastern Europe, whereas decreases were experienced in the southern United States and South America.

Regardless of the reasons for increases, the general approach of developing design conditions based on analysis of the recent record (25 years, in this case) was specifically adopted for updating the values in this chapter as a balance between accounting for long-term trends and the sampling variation caused by year-to-year variation. Although this does not necessarily provide the optimum predictive value for representing conditions over the next one or two decades, it at least has the effect of incorporating changes in climate and local conditions as they occur, as updates are conducted regularly using recent data. Meteorological services worldwide are considering the many aspects of this complex issue in the calculation of climate "normals" (averages, extremes, and other statistical summary information of climate elements typically calculated for a 30-year period at the end of each decade). Livezey et al. (2007) and WMO (2007) provide detailed analyses and recommendations in this regard.

Extrapolating design conditions to the next few decades based on observed trends should only be done with attention to the particular climate element and the regional and temporal characteristics of observed trends (Livezey et al. 2007).

Episodes Exceeding the Design Dry-Bulb Temperature

Design temperatures based on annual percentiles indicate how many hours each year on average the specific conditions will be exceeded, but do not provide any information on the length or frequency of such episodes. As reported by Hubbard et al. (2004), each episode and its duration for the locations in Table 9 during which the 2001 design conditions represented by the 99.6, 99, 0.4, 1, and 2% dry-bulb temperatures were exceeded (i.e., were more extreme) was tabulated and their frequency of occurrence analyzed. The measure of frequency is the average number of episodes per year or its reciprocal, the average period between episodes.

Cold- and warm-season results are presented in Figures 5A and 5B, respectively, for Indianapolis, IN, as a representative example. The duration for the 10-year period between episodes more extreme than the 99.6% design dry bulb is 37 h, and 62 h for the 99% design dry bulb. For the warm season, the 10-year period durations corresponding to the 0.4, 1, and 2% design dry bulb, are about 10, 12, and 15 h, respectively.

Although the results in Hubbard et al. (2004) varied somewhat among the locations analyzed, generally the longest cold-season episodes last days, whereas the longest warm-season episodes were always shorter than 24 h. These results were seen at almost all locations, and are general for the continental United States. The only exception was Phoenix, where the longest cold-season episodes were less than 24 h. This is likely the result of the southern latitude and dry climate, which produces a large daily temperature range, even in the cold season.

7. OTHER SOURCES OF CLIMATIC INFORMATION

Joint Frequency Tables of Psychrometric Conditions

Design values in this chapter were developed by ASHRAE research project RP-1699 (Roth 2017). The frequency tables used to calculate the simple design conditions, and the joint frequency matrices used to calculate the coincident design conditions, are available in ASHRAE's Weather Data Viewer 6.0 (WDView 6.0) (ASHRAE 2017). WDView 6.0 gives users full access to the frequency tables and joint frequency matrices for all 8118 stations in

Licensed for single user. © 2021 ASHRAE, Inc.

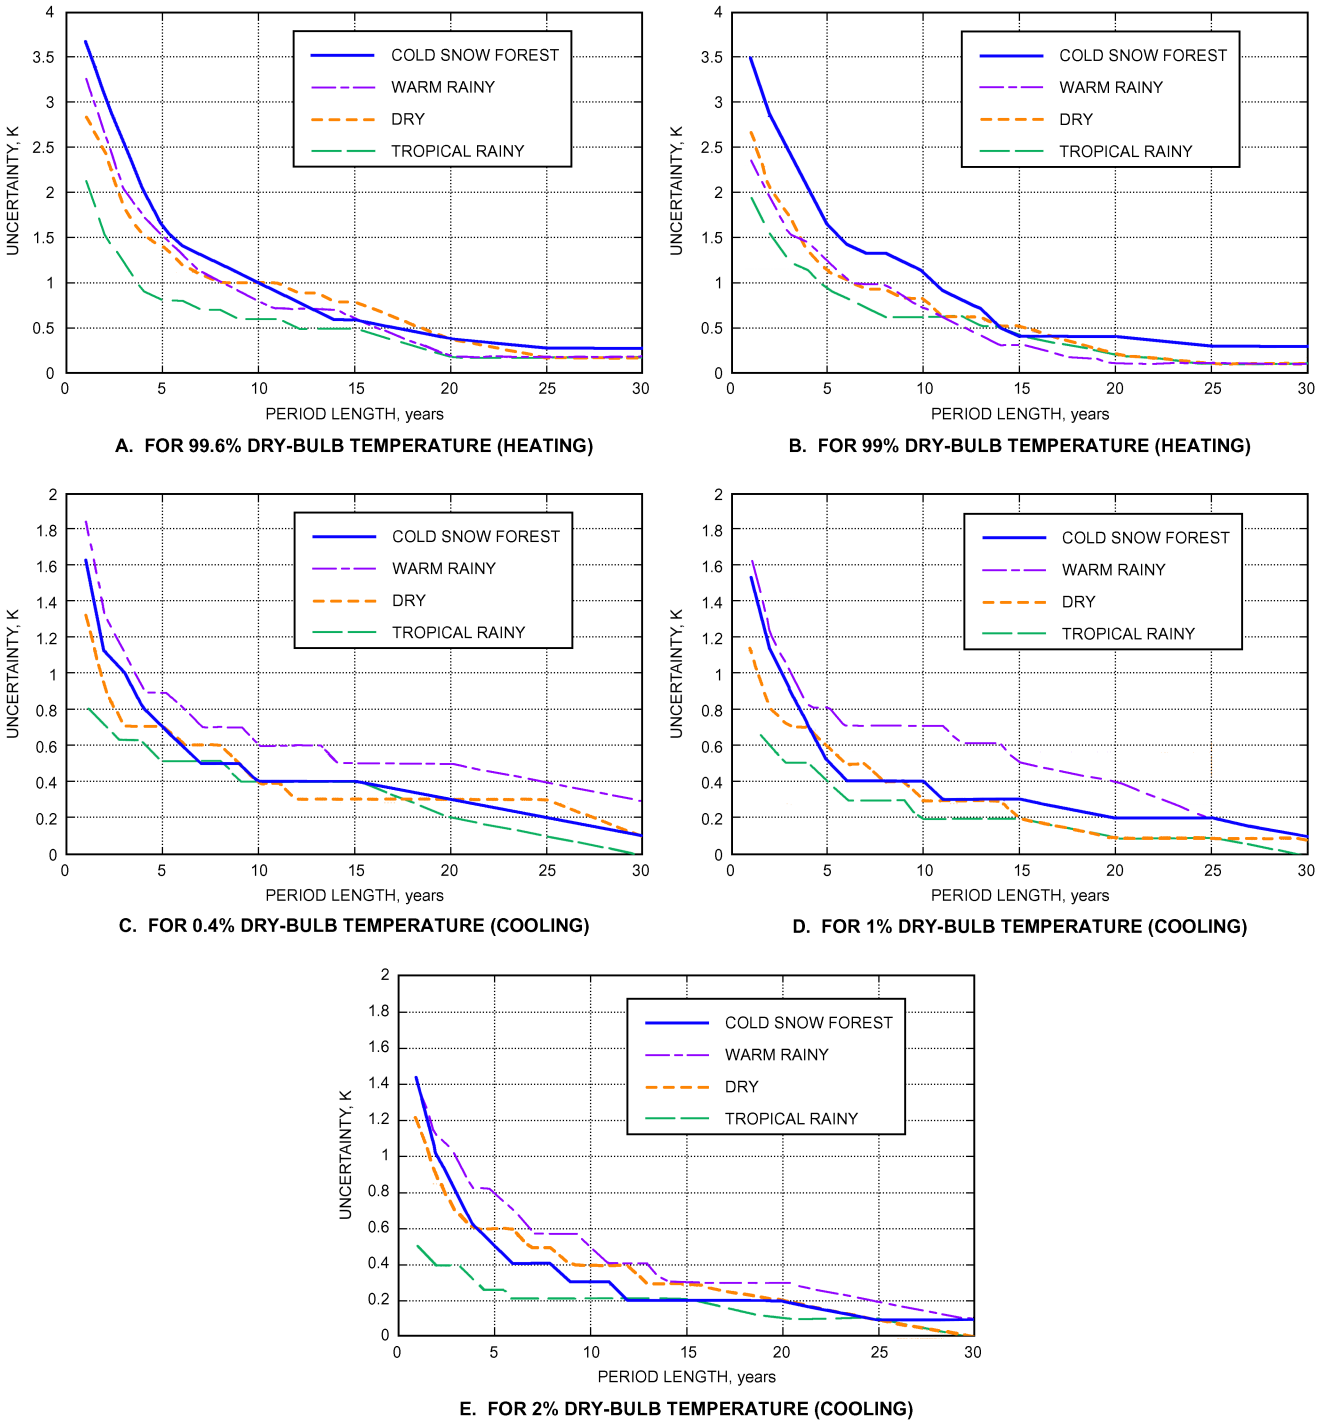

Fig. 4 Uncertainty versus Period Length for Various Dry-Bulb Temperatures, by Climate Type

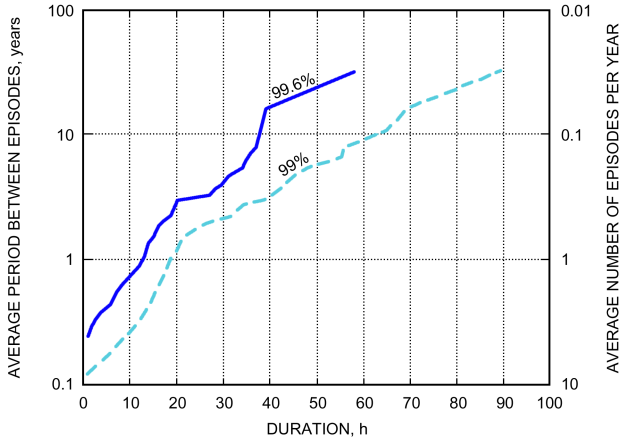
the 2017 *ASHRAE Handbook—Fundamentals* via a spreadsheet, and provides the following capabilities:



- Select a station by WMO number or region/country/state/name or by proximity to a given latitude and longitude.
- Retrieve design climatic conditions for a specified station, in SI or I-P units.
- Display frequency vectors and joint frequency matrices in the form of numerical tables.
- Display frequency distribution and the cumulative frequency distribution functions in graphical form.
- Display joint frequency functions in graphical form.
- Display the table of years and months used for the calculation.
- Display hourly binned dry-bulb temperature data.
- Calculate heating and cooling degree-days to any base, using the method of Schoenau and Kehrig (1990).

The **Engineering Weather Data CD** (NCDC 1999), an update of Air Force *Manual* 88-29, was compiled by the U.S. Air Force 14th Weather Squadron. This CD contains several tabular and graphical summaries of temperature, humidity, and wind speed information for hundreds of locations in the United States and around the world. In particular, it contains detailed joint frequency tables of temperature and humidity for each month, binned at 0.5°C and 3 h local time-of-day intervals. This CD is available from NCDC: www.ncdc.noaa.gov/nespls/olstore.prodspecific?prodnum=5005.

The **International Station Meteorological Climate Summary (ISMCS)** is a CD-ROM containing climatic summary information for over 7000 locations around the world (NCDC 1996). A table providing the joint frequency of dry-bulb temperature and wet-bulb temperature depression is provided for the locations with hourly observations. It can be used as an aid in estimating design conditions for locations for which no other information is available. The CD is available at gcmd.nasa.gov/records/GCMD_gov.noaa.ncdc.C00268.html. A web version of this product is now available free of charge from NCDC at www7.ncdc.noaa.gov/CDO/cdoselect.cmd?datasetabbv=SUMMARIES. This service is also available via gis.ncdc.noaa.gov/map/viewer.

The monthly frequency distribution of dry-bulb temperatures and mean coincident wet-bulb temperatures for 134 Canadian locations is available from Environment Canada (1983-1987).

Degree Days and Climate Normals

The 1981 to 2010 climate normals for over 6000 United States locations are available online (free of charge) from the National Climatic Data Center: gis.ncdc.noaa.gov/map/viewer/.

The Canadian Climate Normals (updated every 10 years; the most recent values are for the 1981-2010 period) can be found at climate.weather.gc.ca/climate_normals/index_e.html.

The *Climatography of the United States* No. 20 (CLIM20), monthly station climate summaries for 1971 to 2000 are climatic station summaries of particular interest to engineering, energy, industry, and agricultural applications (NCDC 2004). These summaries contain a variety of statistics for temperature, precipitation, snow, freeze dates, and degree-day elements for 4273 stations. The statistics include means, medians (precipitation and snow elements), extremes, mean number of days exceeding threshold values, and heating, cooling, and growing degree-days for various temperature bases. Also included are probabilities for monthly precipitation and freeze data. Information on this product can be found at www.ncdc.noaa.gov/oa/documentlibrary/pdf/eis/clim20eis.pdf. Note that this is for 1971 to 2000 and not for the 1981 to 2010 period (latest normals) noted previously.

Heating and cooling degree-day and degree-hour data for 3677 locations from 115 countries were developed by Crawley (1994) from the Global Daily Summary (GDS) version 1.0 and the International Station Meteorological Climate Summary (ISMCS) version 4.0 data.

Typical Year Data Sets

Software is available to simulate the annual energy performance of buildings requiring a 1-year data set (8760 h) of weather conditions. Many data sets in different record formats have been developed to meet this requirement. The data represent a typical year with respect to weather-induced energy loads on a building. No explicit effort was made to represent extreme conditions, so these files do not represent design conditions.

The National Renewable Energy Laboratory's (NREL) TMY3 data set (Wilcox and Marion 2008) contains data for 1020 U.S. locations. TMY3, along with the 1991-2010 National Solar Radiation Data Base (NSRDB) (NREL 2011), contains hourly solar radiation [global, beam (direct), and diffuse] and meteorological data for 1454 stations; TMY3 is available at rredc.nrel.gov/solar/old_data/nsrdb/1991-2005/tmy3/, and the NSRDB at www.ncdc.noaa.gov/land-based-station-data/solar-radiation/. These were produced using an objective statistical algorithm to select the most typical month from the long-term record. A more recent source of *gridded* weather, solar radiation, and environmental TMY data with a visual and dynamic interface is available from maps.nrel.gov/nsrdb-viewer. The solar radiation data are derived from satellite data, and the environmental data are downscaled from the MERRA reanalysis data set derived from a large climate forecasting model (Rienecker et al. 2011). The grid spacing for this source of data is about 4 km, and currently covers North America up to 50° N, as well as a part of South America down to 10° S. Various types of TMY data are available there, currently for the period 1998 to 2014, as well as each historical year within that time period, with anticipated annual updates.

Canadian Weather Year for Energy Calculation (CWEC) files for 47 Canadian locations were developed for use with the Canadian National Energy Code, using the TMY algorithm and software (Environment Canada 1993). Files for 75 locations are now available.

ASHRAE's International Weather for Energy Calculations (IWEC2) data set (Huang et al. 2014) contains typical-year weather data for 3012 international locations outdoor of the United States and Canada. The IWEC2s were developed through ASHRAE RP-1477, which used the same source of raw weather data (ISD; Lott et al. 2001) as used for the design condition tables in this chapter,

Licensed for single user. © 2021 ASHRAE, Inc.

but for a slightly earlier time period of 12 to 25 years ending in 2009. The IWEC2 data set is available on a DVD from the ASHRAE Climate Data Center at www.ashrae.org/resources--publications/bookstore/climate-data-center#iwec; individual files and country sets are also available online from commercial resellers.

Sequences of Extreme Temperature and Humidity Durations

Colliver (1997) and Colliver et al. (1998) compiled extreme sequences of 1-, 3-, 5-, and 7-day duration for 239 U.S. and 144 Canadian locations based independently on the following five criteria: high dry-bulb temperature, high dew-point temperature, high enthalpy, low dry-bulb temperature, and low wet-bulb depression. For the criteria associated with high values, the sequences are selected according to annual percentiles of 0.4, 1.0, and 2.0. For the criteria corresponding to low values, annual percentiles of 99.6, 99.0, and 98.0 are reported. Although these percentiles are identical to those used to select annual heating and cooling design temperatures, the maximum or minimum temperatures within each sequence are significantly more extreme than the corresponding design temperatures. The data included for each hour of a sequence are solar radiation, dry-bulb and dew-point temperature, atmospheric pressure, and wind speed and direction. Accompanying information allows the user to go back to the source data and obtain sequences with different characteristics (e.g., different probability of occurrence, windy conditions, low or high solar radiation). These extreme sequences are available on CD (ASHRAE 1997).

These sequences were developed primarily to assist the design of heating or cooling systems having a finite capacity before regeneration is required or of systems that rely on thermal mass to limit loads. The information is also useful where information on the hourly weather sequence during extreme episodes is required for design.

Global Weather Data Source Web Page

Because of growing demand for more comprehensive global coverage of weather data for HVAC applications around the world, ASHRAE sponsored research project RP-1170 (Plantico 2001) to construct a Global Weather Data Sources (GWDS) web page. Many national climate services and other climate data sources are making more information available over the Internet. The purpose of RP-1170 was to provide ASHRAE membership with easy access to major sources of international weather data through one consolidated online system. This web page was later updated to better use the resources of the World Meteorological Organization (WMO) and NCDC. The GWDS web page is accessible at www.ncdc.noaa.gov/oa/ashrae/gwds-title.html.

Observational Data Sets

For detailed designs, custom analysis of the most appropriate long-term weather record is best. National weather services are generally the best source of long-term observational data. The National Climatic Data Center (NCDC), in conjunction with U.S. Air Force and Navy partners in Asheville's Federal Climate Complex (FCC), developed the global Integrated Surface Data (Lott 2004; Lott et al. 2001) to address a pressing need for an integrated global database of hourly land surface climatological data. The database of over 20,000 stations contains hourly and some daily summary data from as early as 1900 (many stations beginning in the 1948-1973 timeframe), is operationally updated each day with the latest available data, and is now being further integrated with various data sets from the United States and other countries to further expand the spatial and temporal coverage of the data. For access to ISD, go to www.ncdc.noaa.gov/isd or, for a GIS interface, gis.ncdc.noaa.gov/map/viewer/. For a complete review of ISD and all of its products, go to www.ncdc.noaa.gov/isd.

The National Solar Radiation Database (NSRDB) (www.ncdc.noaa.gov/land-based-station-data/solar-radiation/; maps.nrel.gov/nsrdb-viewer) and Canadian Weather Energy and Engineering Data Sets (CWEEDS) (Environment Canada 1993) provide long-term hourly data, including solar radiation values for the United States and Canada. A previous version of the NSRDB required a modified solar radiation model because of the implementation of automated observing systems that do not report traditional cloud elements. The current NSRDB Data Viewer (maps.nrel.gov/nsrdb-viewer), which is mentioned earlier in the section on Typical Year Data Sets, also contains both solar radiation and environmental data for every year from 1998 through 2014 covering North America up to 50° North, and South America down to 10° South. The solar radiation data are derived from GOES satellites and the environmental data are downscaled from MERRA reanalysis data set.

Considerable information about weather and climate services and data sets is available elsewhere online. Information supplementary to this chapter may also be posted on the ASHRAE Technical Committee 4.2 website, the link to which is available from the ASHRAE website (www.ashrae.org).

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *DP: Dew point temperature, °C*
MCDB: Mean coincident dry bulb temperature, °C
Long: Longitude, ° *HR: Humidity ratio, g of moisture per kg of dry air*
HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day
Elev: Elevation, m *WS: Wind speed, m/s*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days	
						0.4%		1%		2%		0.4%		1%		0.4%			1%			1%	2.5%	5%		
				99.6%	99%	DB / MCWB		DB / MCWB		DB / MCWB		WB / MCDB		WB / MCDB		DP / HR / MCDB			DP / HR / MCDB						HDD / CDD 18.3

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*
